sante-consult-b@ec.europa.eu

Reference: Annex 1 Revision: Manufacture of Sterile Medicinal Products

Dear European Commission:

PDA appreciates the opportunity to provide comments to the February 2020 revision of Annex 1 and continues to support its development. This revision is an extremely important update representing the most recent and relevant guidance for the manufacturing of sterile pharmaceuticals, being applied well beyond the EU by both the industry and Non-EU inspectorates. The inclusion in the Annex 1 Working Group (WG) of experts from the European Commission, the World Health Organisation (WHO) and the Pharmaceutical Inspection Co-operation Scheme (PIC/S) is a welcomed directional move towards a global harmonization of requirements.

This Annex and the guidance it presents will have a great impact on the global industry and product supply for years to come. The EMA set a key objective in its 2015 Annex 1 revision concept paper, to embrace the use of new technologies to prevent detrimental impact on product and to encourage the introduction of new technologies that are not currently covered. The recent pandemic and related drug shortages has further reinforced the importance of the developing and implementing sustainable, effective, modern manufacturing methods to produce sterile product of uncompromised quality. To meet this objective, the Annex must have the clarity and strong scientific foundation to promote innovation, encourage process improvement, and ensure beneficial change. But it must also have the clarity of intent to avoid the non-beneficial modification of manufacturing operations, the addition of unneeded complexity, and the possibility of unnecessary manufacturing/supply disruption. We believe the changes will help EMA achieve its stated objective.

PDA is a non-profit international professional association of more than 10,000 individual member scientists having an interest in the fields of pharmaceutical, biological, and device manufacturing and quality. PDA recommendations were prepared by a committee of experts in sterile pharmaceutical manufacturing, taking into consideration comments received from other subject matter experts, its international membership, and the industry at large. Many of our recommendations have been influenced and reinforced by input received during the workshops, conferences and meetings PDA held throughout the 2017-2020 Annex revision review process.

PDA has attached a table with general and specific comments, recommendations, and justification to further clarify the points made herein. The comments were peer reviewed and approved for use by the PDA Science Advisory Board and PDA Board of Directors consisting of pharmaceutical manufacturing experts. They are based on the goal of assisting in the development of a guidance document that:

- clearly communicates the expectations, minimizing misinterpretation
- is based on scientific knowledge
- encourages innovation and the use of new technologies
- provides for the use of risk assessments in evaluating the applicability of specific requirements
- promotes the prevention of failures, rather than primarily relying on testing and detection

The revision represents significant progress towards this goal. We see much improvement and acceptance of earlier comments. However, because of the complexity of the subject matter, the varying experience of companies, and the interpretation of ancillary inspectorates relying on the Annex, additional clarification is needed. In the absence of modification, there are concerns that some sections of the Annex will create confusion and uncertainty for both the industry and inspectors leading to a focus of resources away from areas where advancements have the greatest impact on both improving the manufacturing process and ensuring long term product supply.

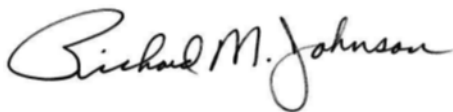

As part of the commenting process, we identified and wish to point out some important concerns that should be further addressed, including (more details are in the comments form):

1. The use of prescriptive requirements and examples (perceived as prescriptive requirements), that may restrict or limit current and future innovative approaches.
2. Mixed messaging on the allowance of alternative approaches based on risk, by alternating a language supporting a risk based approach with very prescriptive requirements.
3. A focus on reactive process monitoring and product testing as a primary means of process control, that results in less emphasis on process design, training and failure prevention.
4. The need for recognition of the impact and feasibility of certain Annex requirements and changes to existing manufacturing processes, facility, and operations, as compared the product quality benefit of those requirements and changes.
5. The need to clarify the intent of and harmonize language in Annex sections, to prevent misunderstandings due to the wide geographical scope of this guidance document
6. The lack of clear distinction between and the perceived grouping of technologies that requires different contamination control strategies, including RABS and isolators, terminal sterilization and aseptic processing, and ATMPs and conventional therapy manufacturing.

Many of the topics presented in the Annex are complex and reflect the need for further discussion and the evaluation of scientific evidence to reach an optimal state of control. Foremost among these is the practical means to achieve contamination free conditions for larger indirect product contact surfaces in isolators, QRM approaches for sterile filtration control and PUPSIT, and best uses and limitations of Aseptic Process Simulations. We encourage a continued dialog with this body, the industry, and other health authorities to further clarify and refine these and other topics in this important Annex.

PDA continues to be committed to assisting in the development of this importance guidance. Upon completion of the revision we remain commitment to assist the EMA (PIC/S and WHO) with any educational, training, or communication efforts required to ensure the correct interpretation and implementation of the principles, recommendations, and requirements presented in the Annex. If there are any questions or any further assistance we can provide, please do not hesitate to contact me.

Kind regards,

Richard Johnson
President & CEO, PDA

SECOND CONSULTATION: STANDBUILDERS CONSULTATION

GMP
Revision to Annex 1
Manufacture of Sterile Products

1. Introduction

The current Annex 1 is being reviewed to better ensure the sterility of medicinal products placed on the market for the benefit of patients. The revision was widely necessary to facilitate implementation of the principles of relevant ICH guidelines, to extend the underlying concepts to include new areas of technology and processing not previously covered and also to clarify areas that have been highlighted as ambiguous due to the age of the document.

In order to maintain the global alignment of standards, achieving at the same time assurance for the highest quality, the Annex 1 Working Group (WG) is made of experts from the European Commission, the World Health Organization (WHO) and the Pharmaceutical Inspection Co-operative Scheme (PIC/S). A first draft of the revised Annex 1 was published for public consultation from 20 December 2017 to 20 March 2018.

Following the consultation of almost 1400 stakeholders and after processing more than 4200 comments the WG issued a revised document, version 12, in November 2019.

Due to widespread interest from industry following the first public publication of the Annex 1, it was found necessary to engage with stakeholders in a second targeted consultation on the updated draft guidance, version 11.

The second consultation aims at collecting experiences from the sectors on certain changes proposed and concerns raised. The consultation representing the sectors most directly concerned and are requested to provide a contribution.

The draft guidelines of version 12 provided has been formatted with paragraph lines and page numbers.

To submit feedback, please provide it exclusively using this dedicated template below.

2. Scope of the consultation

This second consultation is intended to be focused and limited to paragraphs that raised concerns or were changed more significantly, as identified below.

2.1. Feedback on the concerns raised by stakeholders

Qualification & requalification	from § 4.10 to 4.13
Handling of water systems	from § 6.7 to 6.10
Sampling testing of large volumes	§ 6.24
Handling of aerating filter beds	§ 6.90 and 6.91 & 6.96
Handling of lyophilisers	from § 6.100 to 6.111
Handling testing	§ 6.11 & 6.17

2.2. Sections and/or paragraphs which were substantially modified

Definition and handling of bioburden	from § 4.18 to 4.20
Handling of gas filters	from § 6.10 to 6.20 and 6.89 & 6.90
Revised qualification & process	§ 7.1 & 7.6 and from 7.10 to 7.18

	Sample production	Item § 3.11 to 3.19
	Water flow verification	Item § 3.53 to 3.61
	Recessed monitoring	§ 9.12 to 9.13
	Sample process identification (SPI)	§ 9.14 to 9.16 to 9.17
	Quality control	§ 10.1

2.3. Other significant comments

Please avoid re-submitting comments which you already submitted in the first consultation

All documents

3. Name and contact details of the reviewing organization

Please don't add any personal information as the comments might be published

4. Comments

Please enter your comments using the spreadsheet below

Line number (n)	Comments	Suggest form	Justification
-----------------	----------	--------------	---------------

2.4. Feedback on the concerns raised by stakeholders

196.117	<p>In severely tested, the system may be misinterpreted as requiring all of the listed list be performed as a qualification and as well initial qualification of the clean room, when the intent is for it to be initial qualification.</p>	<p>Cleanroom qualification is the overall process of ensuring the level of compliance of a classified cleanroom or clean air equipment with its intended use. As part of the qualification requirements of Annex 10, the initial qualification of cleanrooms and clean air equipment should include (where relevant to the design/operation of the installation):</p> <ol style="list-style-type: none"> leak test (door leakage and integrity testing) Airflow measurement - Volume and velocity Air pressure difference measurements Airflow direction and distribution Microbial airborne and surface contamination Temperature measurement Relative humidity measurement Leakage testing Containment leak testing (where relevant) <p>As per Annex 10, the inclusion of tests for requalification should be justified and the criteria for evaluation defined.</p>	<p>Initial" has been added to the second sentence in the paragraph to clarify that the requirements listed are required for the initial qualification and not necessarily for periodic requalification. It is important to emphasize that these tests provide valuable information on quality and confirm the reliability of performance of the clean room. However, once qualified, the evaluation and analysis of ongoing monitoring should provide evidence that the clean room continues to perform to specified levels. A sentence has been added to the end of the paragraph reinforcing the need to justify requalification criteria. "Where relevant" has been added to the final bullet point in the list to clarify that containment leak testing is only needed where containment is required.</p>
126.427	<p>In severely written, the system may be misinterpreted as requiring the monitoring of a larger particle size, which may not align with supplier recommendations and may not be scientifically beneficial.</p>	<p>For cleanroom classification, the airborne particulates equal to or greater than 0.5 and 1 µm should be measured. For Grade A1 rooms and Grade B1 air, classification should include measurement of particles equal to or greater than 0.5 µm; however, measurements using a second, larger particle size, e.g. 1 µm in accordance with ISO 14644 may be considered. This measurement should be performed both at rest and in operation. The maximum permitted airborne particulate concentration for each grade is given in Table 1.</p>	<p>The reference to 1 µm has been removed, because monitoring that size particle may not be scientifically beneficial. Smaller particle counts are calibrated according to ISO 20108. This note states that during the certification of the size setting, the error in the particle size can be up to ± 10%. Further on, the counting efficiency of a particle counter with a maximum detectable size of 0.5 µm, will only be between 100 ± 10 % for 1 µm particles. By using a second particle size of 1 µm, the obtained values will not be robust as the results will reach the capability of the particle counter itself.</p>
126.424	<p>In severely written, the system may be misinterpreted as recommending the use of the APR for all its operation classification tests of the clean room, instead of referring it as an option for certain procedural related tests. The system may also be misinterpreted as setting an arbitrary limit of 15,20 minutes for the clean room clearing period. In general, the concept procedural are acceptable but need clarification.</p>	<ol style="list-style-type: none"> The definition of "at rest" state is the condition whereby the installation of all the utilities is complete including any functioning HVAC, with the main manufacturing equipment installed as specified and standing by for operation, (where present) in the room. The definition of "in operation" state is the condition where the installation of the cleanroom is complete, the HVAC system fully operational, equipment installed and functioning in the manufacturer's defined operating mode with the maximum number of personnel present performing or simulating routine operational work. In operation classification may be performed during standard operations and certain aspects of the classification confirmed during aseptic process simulation (where tests case simulation is required). The particulate limits given in Table 1 above for the "at rest" state should be achieved after a "clear up" period on completion of operations. The "clear up" period should be determined during the classification of the rooms, documented and referred to in procedures to ensure a qualified state of cleanliness is achieved during operation. (guidance value of 15 to 20 minutes). 	<p>The change clarifies the option for portions of the classification studies to be performed during the aseptic process simulation. While it is an established principle of process validation, that all critical operating systems be qualified prior to the performance of the APR, it may be practical to perform certain aspects of the classification involving presence of cleanroom personnel during the APR. In addition, the guidance value for clearing period has been replaced with language linking the decontamination value to process operation requirements. The current value of 15 to 20 minutes, while not unreasonable in arbitrary and may limit the use of technology in the future. Instead, the important requirement to incorporate wherever value is determined in clean room procedures is emphasized. Substitutes the term "airflow velocity" for "air speed" throughout the document. "Speed" does not define direction while "velocity" does, and, of course, direction is critical to our process.</p>

403.029	<p>In currently written, the section may be misinterpreted as requiring the prescribed guidance value. In addition, in currently written, the section may be misinterpreted as requiring air velocity measurement for non-Grade A areas. In addition, some of the language referring to air speed requires clarification.</p>	<p>The speed acceptable range for velocity of air supplied by Grade A unidirectional airflow systems should be clearly justified in the qualification protocol including the location for air speed measurement. Air flow speed/velocity should be designed, measured and maintained to ensure that appropriate unidirectional air movement provides protection of the product and open components at the working height (e.g. where high risk operations and product surface components are exposed). Unidirectional airflow systems should provide a homogeneous air speed in a range of 0.30 – 0.50 m/s (guidance value) at the working position, unless otherwise scientifically justified in the CCS. Airflow visualization studies should correlate with the air speed measurement. Grade A Unidirectional airflow velocity should be correlated to airflow visualization studies.</p>	<p>"Speed" has been replaced with "velocity" as velocity infers mass, because it refers to a vector quality including both speed and direction. "Grade A" has been inserted in the section, because unidirectional flow may prove to differ than Grade A areas, therefore, it should be clear that these requirements are unique for Grade A and not necessarily for any and all unidirectional airflow systems. The section using the guidance range has been removed, because it may be considered by some to be a generalized range and limit. Airflow velocity should be designed, measured and maintained to ensure that, where it is specified, appropriate unidirectional air movement provides protection of the product and open components at the working height. However, the most suitable velocity range is highly dependent on several factors other than airflow velocity. These include:</p> <ul style="list-style-type: none"> * the individual production equipment calling for Grade A protection * the individual Unidirectional Air Flow Device, UDFD, supplying air * the geometries of the room in which the equipment and UDFD is situated <p>Resolving air flow velocity ranges changes from from the importance of understanding and evaluating the effectiveness of the filter in terms of protecting the product and critical surfaces. Note that the target interval is a kinetic one that does not align with current ISO guidance. The point of concept for the airflow velocity is in the air flow visualization. The correlation between velocity measurements and visualization is key when velocity is used to verify continued compliance with the visualized airflow.</p>
471.050	<p>In currently written, the section may be misinterpreted as relying on the qualification to act to establish microbial contamination levels, rather than to confirm that the adequacy of the controls in place to maintain acceptable environmental conditions.</p>	<p>Environmental monitoring during clean room qualification should demonstrate that the maximum level of microorganisms is not exceeded. The microbial concentration of the cleanroom should be determined as part of the cleanroom qualification. The number of sampling locations should be based on a documented risk assessment, including the results of the classification, air visualization studies and knowledge of the process and operations to be performed in the area. The maximum limits for microbial contamination levels during qualification for each grade are given in Table 3. Qualification should include both at rest and in operation states. Table 3. Limits for microbial contamination during qualification (a) Media plates should be exposed for the duration of operations and changed as required after 4 hours. Exposure time should be based on recovery studies and should not allow detection of the media used. (b) It should be noted that for Grade A, the expected media should be negative. Note 1: All of the typical methods indicated for a specific Grade in the table should be used for qualifying the area of that specific Grade. If one of the methods is not used, an alternative method is used, the approach taken should be appropriately justified. Note 2: Limits are applied using vials throughout the document. If different recovery technologies are used than parent media, in a manner different from vials, the manufacturers should scientifically justify the limits applied and where possible correlate them to vials. Note 3: For qualification of personnel gowning, the limits given for control plates and gown gowns in Table 7 should apply. Note 4: Sampling methods should not pose a risk of contamination to the manufacturing operations.</p>	<p>The first sentence has been replaced to clarify and avoid misinterpretation of the intent of the section. The qualification should confirm the control of microbiological activity in the clean room, not determine or establish these levels. "Of the types" has been added to Note 1 to reinforce that it is the type of monitoring that is important, rather than the specific test. This is needed to allow for the use of alternative methods that may be more effective or more appropriate for a given manufacturing technology today or in the future. Note 3 has been reworded, because it pertains to personnel qualification and monitoring, and section 4.11 addresses cleanroom qualification.</p>

496.112	As currently written, the requirement for requalification intervals for Grade C and D areas is more stringent than ISO 14644 requirements.	<p>The requalification of cleanrooms and clean air equipment should be controlled and periodically following defined procedures. The requirement for requalification of cleanroom areas is as follows: Table 3. Minimum test requirements for the requalification of cleanrooms (image955.jpg)</p> <p>* performed according to a risk assessment documented as part of the CCS. However, required for filling areas (e.g. when filling terminally conditioned products) and background to Grade A RABS.</p> <p>For Grade A & background B areas, the maximum time interval for requalification is 6 months</p> <p>For other Grade B areas, the maximum time interval for requalification is determined in the range from 6 to 12 months in the CCS. For Grade C & D areas, the maximum time interval for requalification is 12 months.</p> <p>For Grade C & D areas, the frequency of the integrity test can be reduced based on good historical performance.</p> <p>Results of routine Environmental Monitoring can be integrated in the requalification plan.</p> <p>Appropriate writing requalification consisting of at least the above tests should also be controlled following completion of remedial action implemented to rectify areas of compliance equipment or facility conditions or other changes to equipment, facility or processes. The significance of a change should be determined through the change management process. Examples of changes to be considered include but are not limited to the following:</p> <ol style="list-style-type: none"> Change in the operational use of the cleanroom, or of the operational writing parameters of the HVAC system. Interruption of air movement which affects the operation of the installation. Special maintenance which affects the operation of the installation (e.g. change of final filters). 	<p>The interval for Grade C and D area requalification should be based on risk based assessment rather than fixed intervals. Where regular microbial monitoring of clean rooms is based upon QM principles and the monitoring data are equivalent to those that are employed in initial qualification the addition of microbial monitoring during area re-qualification is unnecessary. ISO 14644.2 recommends annual re-qualification of clean rooms and allows for a reduction in frequency based upon continued satisfactory performance.</p>
496.436	As currently written, the written water system requirements for prevention of biofilms, which may not be feasible using current technology.	<p>Water produced should comply with the current monograph of the relevant Pharmacopoeia. Water treatment plant and distribution systems should be designed, constructed and maintained to minimize the risk of particulates, microbial contamination/proliferation and pyrogen (e.g. slough of piping to provide complete drainage and the avoidance of dead legs), and prevent minimize the risk of formation of biofilms to ensure a reliable source of water of an appropriate quality. Where filters are included in the system, special attention should be given to the monitoring and maintenance of these filters. Water produced should comply with the current monograph of the relevant Pharmacopoeia.</p>	<p>The last sentence has been moved to the front of the paragraph to emphasize that the primary objective of section 6.7 is to prevent contamination of the criteria for producing water meeting Pharmacopoeia quality standards. Therefore, it is important to emphasize this objective by opening the section with that statement. All the filters helps guide the reader on the means to meet this objective. The word "prevent" has been replaced with the word "minimize", because it may not be possible and may be misleading for companies to think these steps will prevent/biofilm formation. However, it is important that they take actions to minimize the potential formation and then diligently review and monitor the effectiveness of these actions.</p>

606.001	<p>To review the use of examples or other misinterpreted as prescriptive and exclusive requirements, which may limit the use of alternate, innovative, or improved approaches, available and forthcoming.</p>	<p>Where the injections (IFI) should be produced from water meeting specifications, in compliance with the current scope of the relevant Norms/Specs, that have been defined during the qualification process, stored and distributed in a manner which minimizes the risk of microbial growth (for example by constant circulation in a temperature above 5°C). Where the IFI is produced by methods other than distillation, further techniques such as sanitization and sterilization as well as decontamination (DD) should be considered and validated in conjunction with reverse osmosis (RO) membranes.</p>	<p>Norms/specs do define the options for feeding water (DIP, Distilled Water, UF, Distilled or Purified Water, Chlor, Purified Water) for RW plants. Also, the design of the water system must take into account the quality of the feed water and the required characteristics after the treatment (RW). The proposed change concerns the use of examples. It is important to note the use of sanitization and DD may be detrimental and produce additional challenges.</p>
606.002	<p>In currently written, the section sets a requirement for sanitization of raw filters that may not be feasible or necessary.</p>	<p>Where if RW storage tanks are equipped with hydrophobic bacteria sensitive raw filters, the filters should be sanitized and the integrity of the filter tested before installation and after several following use.</p>	<p>'Effectiveness' has been replaced with 'sanitized', because air raw filters should be hydrophobic but need not be microbially sensitive nor do they need to be sterile. RW is by definition microbially and chemically sterile and common storage conditions effectively eliminate microbial growth. Where QRM dictates the use of a microbially sensitive filter, it should be integrity tested periodically to ensure its functionality. The use of raw filters to limit ingress of contaminants should be subject to the principles of QRM. Filter effectiveness by means of integrity testing, where applicable, should be performed. Test results should be interpreted, and appropriate actions taken based upon the risk to water quality and to the ultimate quality of the product.</p>
607.001	<p>To minimize the risk of biofilm formation, sanitization of water treatment and storage/distribution systems should be carried out according to a predetermined schedule or when microbial counts exceed action limits. Distribution of a water system with chemicals should be followed by a validated rinsing/flushing procedure and water should be tested and released for use according to system procedures after distribution/regeneration.</p>	<p>To minimize the risk of biofilm formation, sanitization and distribution or regeneration of water systems should be carried out according to a predetermined schedule and when microbial counts exceed action limits. Distribution of a water system with chemicals should be followed by a validated rinsing/flushing procedure and water should be tested after distribution/regeneration. The results should be approved before the water system is released to use.</p>	<p>Sanitization is used in place of distribution/regeneration because it is BRCGD term which allows for the establishment of microbial limits based on QRM principles. Regeneration and sanitization of water processing steps (filtration, carbon treatment) would not usually comply, nor should they be expected to, with the commonly accepted definition of sanitization (e.g., a specified multi log reduction). The suggested wording also distinguishes water treatment from storage/distribution. It allows for the common practice of continuous rather than periodic sanitization of storage/distribution, such as by line circulation. Approval of the water after chemical sanitization of treatment steps and prior to use may be according to a written procedure that is based on a validated process.</p>

603.072	Generally as written this section may potentially be too prescriptive and may hinder periodic sampling of all points which could be more effective than sampling of one point.	<p>Regular ongoing chemical and microbial monitoring of water systems should be performed. Alert levels should be based on the qualification as a review of ongoing monitoring data that will identify an adverse trend in system performance. Sampling programs should reflect the requirements of the GMP and may include:</p> <ol style="list-style-type: none"> All points of use, at a specified interval, to ensure that representative water samples are obtained for analysis on a regular basis. Strategic water use sampling locations. A sample from at least one critical point of use (the point at the end of the distribution loop each day that the water is used). 	<p>The inclusion of the word “may” allows for latitude in determining the optimal sampling plan depending on process design and operation. The change to subsection (ii) allows for critical daily sampling. The reason that end of loop is selected is that by definition the loop is a continuous process flow circuit, where if designed and operated consistently, any one point of use should have no higher risk than another. The primary purpose of daily sampling is there to measure an indicator or new variable in the system. Therefore, periodic sampling of all points would be more effective than sampling of one point.</p>
603.102	As currently written this section may be misinterpreted as requiring 100% integrity testing of the container once sealed permanently sealed containers, which is not feasible.	<p>Containers should be closed by appropriately validated methods.</p> <ol style="list-style-type: none"> Containers closed by fusion, e.g. Blown/Bilocal (BB), then, Bilocal (BB), Small and Large Volume Blown (SPL & LVP) bags, glass or plastic ampoules, should be subject to 100% integrity testing, or where 100% integrity testing is shown to be not feasible, should be taken and checked for integrity using validated methods. Samples of containers closed by other methods, should be taken and checked for integrity using validated methods. The frequency of testing should be based on the knowledge and experience of the container and closure system being used. A risk/benefit valid sampling plan should be utilized. The sample size should be based on information such as supplier approval, packaging component specifications and process knowledge. It should be noted that visual inspection alone is not considered as an acceptable integrity test method. 	<p>It is not currently feasible to perform 100% integrity testing on all of most the product configurations. For example, many flexible containers (i.e., LVP/BB bags) are placed in overpacks/pieces of material inside heat sterilization to ensure that liquid product formulation containers are stable over the shelf life of the product. With the currently available 100% integrity testing technologies, the application of 100% integrity testing requires a destructive test in the overpack would be required to be removed from units after completion the testing. Although an additional overpack could be supplied after testing, this represents an unnecessary and excessive burden. Additionally, customer parent container (from sites after filling or from main heat sterilization) can often interfere with test results of the currently available integrity test methods (e.g., vacuum decay, manometric, etc.). Due to these examples and the lack of compatibility of various integrity test methodologies, the pharmaceutical industry is not currently prepared to adopt 100% integrity testing for all of the stated container configurations. Preliminary results from the Kilauea Conference BMT and Container Water Heat Practice to Pharmaceutical Industry Awareness Survey (final results to be published as a white paper) provide further confirmation of a lack of ability and readiness of the pharmaceutical industry to adopt the 100% integrity testing requirement. The flexible container, only 1 Respondent (0.5%) currently employed 100% integrity testing while 7 Respondents (35.0%) indicated that it would take 1 or more years to implement this requirement.</p>

1406-1411	<p>While the system is much improved from previous versions, there remain gaps requiring further clarification. These include, the need to emphasize the QRM objective of the system, the removal of examples which may be misinterpreted as exclusively prescribed requirements, the evaluation of risk to aseptic processing if posed by PURST, and some technical modifications.</p>	<p>Within the risk based design of the aseptic filtration process, The air integrity of the sterilized filter assembly should be verified correct. This may be done by integrity testing before use, to check for damage and loss of integrity caused by the filter preparation prior to use. A sterilizing grade filter that is used to sterilize a fluid should be subjected to a non-destructive integrity test post-use prior to removal of the filter from its housing. Integrity test limits should continue to be microbial retention capability of the filter established by the filter supplier during qualification. Test results should continue to be the microbial retention capability of the filter established during validation.</p> <p>Examples of test that are used include bubble point, diffusion flow, water intrusion or pressure hold test. It is recognized that post-use post-sterilization integrity testing (PURST) may not always be possible adequate after sterilization due to process constraints design (e.g. the filtration of very small volumes of solution). In these cases, an alternative approach may be taken providing that a thorough risk assessment has been performed and compliance is achieved by the implementation of appropriate controls to mitigate any risk of non-sterility. Process controls to such a risk assessment of the aseptic filtration process should include but are not be limited to:</p> <ol style="list-style-type: none"> In depth knowledge and control of the sterilization process to ensure that the potential for damage to the filter is minimized. In depth knowledge and control of the supply chain to include: <ul style="list-style-type: none"> - Container sterilization facilities - Delivered transport mechanisms - Packaging of the sterilized filter, to prevent damage to the filter during transportation and storage. In depth process knowledge such as: <ul style="list-style-type: none"> - The specific product type, including particulate burden and whether there exists any risk of impact on filter integrity values, such as the potential to alter integrity testing values, and therefore prevent the detection of a non-integral filter during a post-use filter integrity test. - Pre-filtration and processing steps, prior to the sterilizing filter, which could remove particulate burden and clarify the product prior to the main filtration. <p>- Risk to the aseptic process</p>	<p>Sterilizing grade filtration is a critical process which requires a comprehensive, end-to-end risk based design. Emphasis should be put on prevention of failures throughout all the filter lifecycle. It is acknowledged that integrity testing of the filter assembly is an important step to confirm effectiveness of the filtration process. It is generally recognized that post-use filter integrity testing is sufficient to detect filter failure and ensure patient safety unless there is a possibility that a filter passing the post-use test could have allowed bacterial penetration during filtration. This possibility is the phenomenon referred to as filter "flow marking". Hypothesized to occur when, for example, a filter is damaged during sterilization such that it allows bacterial penetration, but that the damage becomes plugged during the filtration process to such an extent that it allows the filter to exhibit a passing post-use integrity test result. For this marking phenomenon to occur, two conditions must exist: first, there must be a flaw in the filter that is large enough to allow bacterial penetration during use, yet small enough to be plugged during the filtration process. Second, the product being filtered must be capable of blocking the flaw to the extent that it still pass a post-use integrity test. Studies have been performed and data collected by FDA and the Biopharmaceutical Convention to identify when such marking circumstances may occur, and as such when performing a flow flow, post-sterilization integrity testing is adequate. These studies show that the occurrence of potential marking conditions would be extremely rare, predictable and controllable (see FDA/Biopharmaceutical Conventions dual marking study and ICHT paper). Integrity test immediately after filter sterilization can help identify filter issues before use, however such test put at additional complexity to the process and can increase the risk of product contamination due to the additional manipulation/ disturbance of the sterilizing filter. FDA and Biopharmaceutical Convention conducted a series of industry surveys and prepared a comprehensive PURST flow Practice Points to Clarify report that presents levels of complexity that can pose a risk to the aseptic process. In addition, FDA and Biopharmaceutical Convention issued guidance that indicates adequate levels of control. (see FDA/Biopharmaceutical Conventions dual marking study, FDA's and Best Practice (BPC)).</p> <p>A comprehensive control strategy should consider all the above and identify the most suitable approach for each product and manufacturing process, and the preventive measures and controls to be in place from the filter manufacturing, to its sterilization and use, up to the post-use testing, to ensure product sterility.</p> <p>In addition, the integrity test limits are established by the filter manufacturer during their qualification activities and are during the process validation at the customer site. The intended outcome centers clarity on that point.</p>
1407-1408	<p>In currently written, the system may be misinterpreted as requiring filters be discarded after each lot during a multiple lot campaign.</p>	<p>Single sterilizing filters should be discarded after the processing of a single lot unless validated for campaign manufacture and the same filter should not be used for more than one working day unless such use has been validated.</p>	<p>Revision for multiple lot campaigns has been added to the section, because there are specific filtration processes, which utilize the filter for more than one batch, for a campaign. These campaigns are has to be process validated meaning good batch to prove that the filter will function as specified over the entire campaign.</p>

1001, 1002	As currently written, the section could be misinterpreted as requiring the QR to include the time between the start and end of multiple verification processes and holding times. Or the duration between verification cycles when the hypothesis is not used and not supposed to remain viable.	The verification of hypothesis and associated equipment (e.g. trays, trial support trays) should be validated and the holding times between verification cycles and the use of loading should be included in the appropriately challenged during aseptic process simulations. The hypothesis should be verified regularly, based on system design. Re-verification should be performed following maintenance or cleaning. Sterilized hypothesis and associated equipment should be protected from contamination after verification.	The conditions and time between the end of a given hypothesis verification and the start of the loading of that hypothesis is the critical aspect of the process that should be addressed in the section. Clarification of what is the intended holding time referenced in the section and included in the aseptic process simulation is important.
1001, 1002	As currently written, the section may be misinterpreted as requiring additional sterility testing after any intervention. In addition, as currently written, the section implies that it is feasible and scientifically beneficial to test samples from "warm zone" locations throughout a terminally sterilized product load.	<p>The sterility test should be performed under aseptic conditions. Samples taken for sterility testing should be representative of the volume of the batch but should in particular include samples taken from parts of the batch considered to be most at risk of contamination, for example:</p> <ol style="list-style-type: none"> The products which have been filled aseptically, samples should include containers filled at the beginning, middle and end of the batch and after an activity or event assumed to pose a risk to the sterility of the product, when the testing of product immediately after the activity and event would provide valuable information for determining its impact on product sterility; any significant intervention (e.g. interventions where the integrity of a barrier is breached (open door) or an operator intervention into critical zones). Where warm zone locations have been identified in the unit or in load The products which have been least verified in their final containers, samples taken should be representative of these locations. warm zone locations where (e.g. for unit) or within with defined the potentially critical or at-risk to heat part of each load. The products that are hypothesis, samples taken from different hypothesis loads. <p>Note: Where the manufacturing process results in sub-batches that represent an increased or variable risk to product sterility, (e.g. for terminally sterilized products) then sterility samples from each sub-batch should be taken and a sterility test for each sub-batch performed. Consideration should also be given to performing separate testing for other finished product lots.</p>	<p>Explanation for proposed change to section 10.1 (ii)</p> <p>Although some uniters contain identified and event designed (e.g., pre-wash, uniters drain) there is heat locations or cold spots, not all uniters contain warm zone locations due to uniters and process design. Examples of uniters that may not contain consistent warm zone heating locations include some rotary and some immersion uniters which feature active water circulation to ensure a uniform distribution of the heating medium across the uniters and product.</p> <p>Explanation for proposed change to section 10.1 Note</p> <p>The statistical and detection sensitivity limitations of the finished product sterility test are well known, and it is universally accepted that this test is incapable of providing support for a high sterility assurance level in terminally sterilized products. Section 10.1 appropriately emphasizes the achievement of critical parameters as the primary means for demonstration of product sterility. In the development of any sampling plan, the principles of QRM may be employed to ensure proper product representation to support the effective diagnosis for any product uniters including sterility.</p> <p>In situations where multiple uniters (properly maintained, operated, calibrated and qualified) are utilized with an identical recipe of uniters parameters to produce product from a single batch, the level of risk mitigation provided by performing a sterility test on each uniters load for a batch provides an insignificant incremental level of assurance of sterility when compared to a sterility test involving at least a single product unit from each uniters load from the batch. An increase in the number of samples associated with a requirement for a full sterility test the volume of a batch represents an unnecessary proliferation of a scientifically based practice without providing an associated patient benefit commensurate with the increased burden of testing.</p> <p>The requirement for sterility test after "any significant intervention" is replaced in subsection (i) with risk assessment language encompassing the understanding of the intent and benefit of the test. The proposed change clarifies the use of sterility test after interventions, with proper assessment and CCS understanding, while avoiding the following unintended consequences of the current language.</p> <p>Without the proposed change, some companies and others would have trouble defining a "significant intervention", opting instead for pulling sterility samples after interventions that pose little risk and with little benefit. Because the removal of intervention samples involves an activity (to remove the critical zone), this activity itself poses a risk to the sterility of product. (2) Without the proposed change, some companies and others will rely on the sterility test as the indicator of the appropriateness of the intervention and its effect on subsequent filled product. It is important for companies to understand that the sterility test is a statistically limited analysis designed to verify the batch, it is not designed to be a means to evaluate the appropriateness or performance of process activities or interventions. Confidence in the appropriateness of interventions, activities, and control measures should be obtained through process design, performance and monitoring, rather than testing of product. (3) Without the proposed change, some companies will as define, or use, non-sterile activities in the critical zones as something other than interventions, in order to avoid performing additional sterility tests, therefore not performing other controls and assessments needed for such interventions.</p>
2.2. Section and/or paragraphs which were substantially modified			

102.128	<p>Section 4.18, as currently written, may be interpreted as governing BARE and isolators as equal technologies.</p> <p>In addition, section 4.18, as currently written, may be interpreted as limiting the technology available for transfer of materials to rigid transfer and transfer isolators. The mention of only two systems, may stymie companies from exploring and using innovative solutions.</p>	<p>Isolator or BARE, which are non-direct technologies, and the associated process, should be designed to provide protection of the Grade A environment from contamination. The entry of materials during processing (and after decontamination) should be minimized and preferably supported by systems that prevent contamination.</p>	<p>The first change reinforces that it is important for the reader to recognize that while BARE and isolators are both barrier systems used to separate personnel from the aseptic process, they are not very distinct technologies and the controls required for both are different.</p> <p>The second change allows for the use of support systems and procedures beyond those specifically mentioned, thus allowing for innovative approaches that are or may be available.</p>
102.140	<p>Section 4.20, as currently written, does not require the unidirectional airflow in open isolators, where it may not be necessary or in some cases not feasible to have traditional unidirectional airflow due to the confined space and configuration.</p>	<p>In operation, The risk critical zone of the a BARE or open isolator used the aseptic process should meet Grade A requirements where with unidirectional airflow. The critical zone of an isolator in operation should meet Grade A requirements, and where the process design and controls require, have unidirectional airflow. In isolator systems where airflow may not be unidirectional, it should provide Grade A conditions and be demonstrated to provide adequate protection for exposed product during processing. The design of the BARE and open isolators should ensure a positive airflow from the critical zone to the supporting background environment (unless containment is required in which case localized air restriction is required to prevent contamination transfer to the surrounding room). Negative pressure isolators should only be used when containment of the product is considered essential and risk control measures are applied to ensure the critical zone is not compromised.</p>	<p>"In operation" has been added to the first sentence to clarify that BARE critical zones should meet Grade A and be unidirectional air during operation. The reference to open isolators has been removed from the first sentence and the second sentence modification include both open and closed isolators, and requiring unidirectional airflow where needed, because most open isolators are essentially closed, with openings only for the removal of sealed product. In these systems, it is not necessary or in some cases not feasible to have traditional unidirectional airflow due to the confined space and configuration. Filtered air, with proper flow and pressure, that is not unidirectional can still provide required level of cleanliness and Grade A conditions in well designed and demonstrated isolators. The strict requirement for unidirectional airflow in all isolators will be difficult to achieve and demonstrate; and may have the unintended consequence of diminishing the development and use of innovative isolator designs that use smaller critical spaces. Smaller critical spaces are important, because they are less complex and limit exposure of product to environment. The proposed change removes the limitation of unidirectional airflow for isolators, thus allowing the use of innovative isolator technology and designs.</p>
102.145	<p>The section, as currently written, uses language that is not consistent with current use in section 4.21. The section also seems to indicate that open door interventions may be performed on or in isolators.</p>	<p>The BARE used for aseptic processing, the background environment should meet or have controlled to a minimum Grade B and airflow studies to (2) airflow studies should be performed to demonstrate the absence of air ingress during interventions, such as door openings for BARE and open isolators. The background environment for open isolators should meet controlled to Grade C or D) based on a risk assessment.</p>	<p>The proposed change replaces "near" with "controlled or" - in order to be consistent with the wording used in section 4.21 and eliminates the potential misunderstanding of open door interventions.</p>

M7.101	In severely wetted, the section may be misinterpreted as pertaining only to closed isolators.	The background environment of a closed isolator should correspond to a minimum of Grade B. The distribution/contamination programme should be included as a key consideration when performing the risk assessment for the CCR of an open and closed isolators. Where additional process risks are identified, a higher grade of background should be considered. The decision as to the supporting background environment should be documented in the CCR.	The change clarifies the intent of the section by adding closed and open isolators.
M7.102	The P&ID expert considers found this section difficult to understand and open to interpretation. This is an important section containing valuable guidance and clarification would be beneficial. There is also a concern that the section as written may be misinterpreted as requiring the use of mechanical methods over the integrity of fixed RAB gloves after interventions.	The materials used for glove systems in isolators and RABs should have mechanical and chemical resistance adequate for their purpose. The materials used for glove systems (the both RABs and isolators), as well as other parts of an isolator, should be documented to have good mechanical and chemical resistance. The frequency of glove replacement should be based upon risk of failure, device size, and criticality of usage as defined within the CCR. The isolator exterior handle should be sealed to confirm absence of air leakage and the integrity of fixed gloves used in isolators and RABs should be confirmed by test or other methods documented to be suitable for the risk and criticality of the glove design and usage. Integrity testing of the handle systems, and leak testing of the glove system and the isolator should be performed using a methodology documented to be suitable for the risk and criticality. The testing should be performed at defined points (based on an assessment of process and product risk). The integrity of fixed gloves should be tested at a minimum upon installation, at the beginning and end of each batch or manufacturing campaign, and after an activity assessed to pose a risk to the integrity of the fixed glove. Where RABs are located in Grade B areas with environmental controls in place and the presence of air instrumentation may add risk during manufacturing, visual examination may be used to test the integrity of the fixed gloves between batches. The testing should be performed at defined points, at a minimum at the beginning and end of each batch, and should include a visual inspection following any intervention that may affect the integrity of the system. For single unit batch sites, integrity may be verified based on other criteria, such as the beginning and end of each manufacturing system. RAB gloves used in Grade A areas should be verified before installation and verified (or collectively demonstrated) by a validated method which achieves the same objective) prior to each manufacturing campaign. The frequency of glove replacement should be defined within the CCR.	The changes have been made to reinforce the use of risk-based approaches. Because of the RAB design and placement in the clean room, use of instruments and equipment used to perform mechanical integrity testing of gloves may compromise the sample processing environment and quality of product. The proposed change presents the section in a more understandable form and clarifies the requirement for inspection of gloves after some interventions or during a campaign. There is also a concern that integrity testing of isolator gloves during a batch or campaign would inflate and may over-preserve gloves which may pose a risk to the integrity of the fixed gloves. It is also noted that for both RABs and isolators it may not be possible to do a physical integrity test during the batch or campaign without a risk to product sterility.

798.798	<p>In currently written, the section sets a requirement for placement of gas filters at point of use, which may not always be feasible or advisable. In addition, the section requires microbiological monitoring of the gas, which may not be necessary for properly designed and integrity tested systems.</p>	<p>Clear text in aseptic processes should be filtered through a sterilizing filter (with a nominal pore size of a maximum of 0.22 µm) at point of use located as close as possible to the number of aseptic connections required between the sterilizing filter and the point of use. Where the filter location is fixed/locks (e.g. the filtration of gas used for control of aseptically filled products) or aseptic vessel vent filters, then the filter should be integrity tested and the results included as part of the batch certification process. Any number pipework or tubing that is located after the final sterilizing filter should be certified. When gases are used in the process, microbial monitoring of the gas should be performed periodically at the point of use.</p>	<p>the point of use" has been replaced with risk based language to allow for more effective process design and align with product filter location related language appearing elsewhere in the Annex. The requirement for monitoring has been removed, because sterilizing filters that have been validated for gas service and are integrity tested to ensure effectiveness, should achieve the need to maintain the gas for microbial contamination.</p>
798.799	<p>Section 7.8 updates an impurities text previous language. It contains impurity guidance and points the industry. However, during the ICH expert committee review, it became apparent that there remained significant points where clarification is needed. To that end recommend the other noted proposed change and the following explanation.</p>	<p>The section in Guide A and Guide B cover where aseptic operations are or will be conducted should be monitored by appropriately qualified personnel. Companies should establish written procedures for the qualification of personnel commensurate with the stated level of risk of their job function. These procedures should take into consideration requirements for training, classroom education appropriate training/qualification, the level of supervision, and a demonstrated aseptic proficiency in the performance of aseptic process activities demonstrated by either successfully performing a qualification test involving manual media manipulation or associated with a full aseptic process simulation (APS) or have participated in a successful aseptic process simulation test. Where required, compliance with aseptic training procedures should be assessed and confirmed, periodically reassessed at least annually and should include both visual and microbial assessment using monitoring locations such as health, arms, chest and forehead. Refer to paragraph 7.50 for the expected limits.</p>	<p>Section 7.8 updates an impurities text previous language. It contains impurity guidance and points to industry. However, during the ICH expert committee review, it became apparent that there remained significant points where clarification is needed. To that end recommend the other noted proposed change and the following explanation.</p> <ol style="list-style-type: none"> 1. The opening sentence of 7.8 refers to "access to the Grade A zone". This refers that classroom personnel are permitted to be present in the Grade A zone during aseptic operations. This is probably not the intent. To clarify intent, we recommend adding the paragraph with a remainder of the sentence. 2. Further in that sentence, there is a requirement the aseptic training facility. However, those working in the Grade A zone or an isolator should not require aseptic training or where training. To clarify intent, we recommend a note on where training is required. 3. Personnel not performing activities during the aseptic operation (e.g. off shift cleaning/maintenance and maintenance personnel) should not be deemed as unqualified and require constant supervision, if they do not participate in an APS. There is no benefit as it is feasible for these personnel to perform their non-aseptic processes during an APS. To clarify intent, we recommend the qualification for commensurate with the stated level of risk of their job function. 4. We are concerned that the requirement for qualifying classroom personnel through participation in an APS will result in many GMP companies having to interrupt production operations to accommodate additional long duration APS studies to qualify new classroom personnel. Because many of these operations occur in classrooms with multiple BSCs, this interruption will result in a reduction of output of needed medicines/therapies. In addition, training on schedule APS will reduce the ability to add classroom personnel. This will have a direct effect on output of these therapies. To avoid this unintended negative consequence, we recommend the alternative methods for classroom personnel qualification be allowed, as noted in the proposed change. 5. In general, we are concerned that the requirement for participation in the APS motivates companies to focus on the APS as the primary means to qualify personnel. Because the APS is not designed nor sensitive enough to demonstrate the qualifications of classroom personnel, the primary use of APS for personnel qualification will divert efforts from more useful methods and provide inaccurate process confidence. To avoid this misperception, we recommend the replacement of the requirement for the APS with a requirement for demonstrating aseptic proficiency. This allows companies to continue to use the APS, if warranted, but adds the flexibility to develop and use more modern and effective classroom personnel qualification methods. 6. It is important to note that the proposed addition of "to demonstrate aseptic proficiency in the performance of aseptic process activities" in place of the requirement for "participation in a successful aseptic process simulation (APS)" is not designed to prohibit the use of APS. Rather it is designed to allow companies the ability to design and use the most effective means to demonstrate aseptic process performance. Companies can certainly opt to use the APS, if they find that to be valuable and appropriate.

451.485	As currently written, the section may be misinterpreted as requiring the qualification include a determination being long the greatest can be seen.	Every operator meeting Grade II or C/II/DS	The wording of the last sentence clarifies that the intent of the section is that the qualification should be used to verify the maximum run, cooling cycles, and certifications, unless that time it can be seen.
451.477	As currently written, the section requires clarification to include the paper documentation and inclusion of duration in the aseptic process.	<p>The duration of each aspect of aseptic preparation and processing should be established and defined by a method deemed appropriate by the CCS. The CCS should address the following: limited to a defined and validated maximum time including but not limited to:</p> <ol style="list-style-type: none"> The holding times between equipment, components, and containers cleaning, drying and sterilization. The holding times for sterilized equipment, components, and containers before use and during filling/assembly. The holding times for a decontaminated environment, such as the BARR and isolator before and during filling/assembly. The time between the start of the preparation of a product and its sterilization or filtration through a microorganism-retaining filter (if applicable), through the end of the aseptic filling process. There should be a maximum, practical time for each product that takes into account its composition and the practical method of storage. The holding time for sterilized product prior to filling. The aseptic processing time. The filling time. The maximum exposure time of sterilized containers and closures in the critical processing zone (including filling) prior to closure. 	<p>There are three changes recommended to clarify the intent of the section. "Each" has been removed in the opening sentence, because the relevance of the duration of given aspect or activity of the aseptic process varies in importance according to that aspect or activity. Some durations should be defined and some not. Drying and maintaining durations that are not important may limit manufacturing output or efficiency. "Limited to a defined and validated maximum time" has been replaced with "established and defined by a method deemed appropriate by the CCS" in the opening sentence, because time is not validated, it is a process with an established time that is validated. Added explicit reference to the Commission's Closed Strategy as the basis for the selection of the most appropriate approach to demonstrate the suitability of the mentioned hold times. "The limited to" have been added to the end of the last sentence to allow for inclusion of other aspects or activities not mentioned in the current text. Subsection viii has been removed, because it is covered by aseptic processing time in subsection vi. In addition, it would not be feasible to accurately determine a maximum exposure time for all sterilized components, because in theory given time and aseptic may remain as reasonable as in a supply line for the entire run.</p>
1208.1207	As currently written, this section may be misinterpreted as incorrectly indicating that the drain at the bottom of the chamber is always a coldtrap when temperature recording is required. While this is may be correct for pressure sensitive, this is not always case with sophisticated technology or more immersion methods.	The chamber capable of performing pressure sensitive cycles listed with a drain at the bottom of the chamber, the temperature should be recorded at the chamber drain this position throughout the sterilization period. For areas in place systems, the temperature should be recorded at condenser drain locations throughout the sterilization period.	Clarifications have been made to indicate that the requirement for recording temperature at the drain is relevant to pressure cycle controllers. The drain at the bottom of the chamber for pressure sensitive is the normally occurring coldtrap for this pressure sensitive due to the design where air and condensate are controlled to pool in this location followed by subsequent removal from the chamber. A drain at the bottom of the chamber for other types of sensitive may not always be the condenser/coldtrap and a new coldtrap may not exist for certain sensitive types. For example, sophisticated technology sensitive operate with a specified level of water in the vessel and the underdrain at the bottom of the chamber is connected to a recirculation spray loop and this chamber under/drain may not be a sensitive coldtrap.

1208.1202	As currently written, the section does not clearly define critical processing parameters and equilibration time could be incorrectly interpreted to be included.	Validation of process cycles should include a calculation of equilibration time, exposure time, combination of pressure and temperature and maximum temperature range during exposure. Validation of fluid cycles should include temperature, time and/or flow. These critical processing parameters should be subject to defined limits (including appropriate tolerances) and be confirmed upon all the sterilization validation and routine cycle acceptance criteria, as applicable .	As applicable has been added to the end of the section, because equilibration time can only be calculated through the use of heat penetration probes in product which is not always the case with routine cycles.
1208.1203	As currently written, the example in the section may be misinterpreted as being a prescriptive and exclusive requirement.	Leak tests on the sterilizing system should be carried out periodically (usually weekly) when a vacuum phase is part of the cycle or the system is vented, post-sterilization, to a pressure lower than the environment surrounding the sterilized system.	The example has been removed, because the specified weekly frequency for the leak test is excessively prescriptive. The frequency of the leak test and other sterility monitoring tests should be based on QRM principles and tailored to each specific unit/line. For example, a weekly frequency may not be necessary for modern well-maintained pharmaceutical unit/lines while a frequency greater than weekly could be necessary for older unit/lines.
1208.1204	As currently written, the section includes examples that are open to interpretation, require clarification to align with intent of the section, and may be limiting in application.	There should be Two process based good leak and SIP cycle validation studies, should provide adequate assurance of air removal prior to and during sterilization when the sterilization process includes stoppage (e.g. process parameter leak, biopharm cleanroom). The assurance, this should include an air removal test cycle on a frequency determined and justified through a risk assessment (normally performed on a daily basis) or an air detector system. Leaks in the sterilized should be designed to support efficient air removal and be free draining to prevent the buildup of condensate.	The examples have been removed and replaced with definitive sterilization circumstances and QRM based criteria, to prevent misinterpretation and improve clarity. The requirement of a daily air removal test is too prescriptive and constrains an unnecessary burden the companies that utilize modern and properly maintained unit/lines and steam supply systems. Adequate air removal is demonstrated with the use of heat penetration probes in product during sterilization validation studies with correlation to critical process parameters. Since heat penetration probes in product and/or air detectors are not utilized in all routine cycles, the achievement of validated critical process parameters provides assurance of air removal. The specified daily frequency for the air removal test is excessively prescriptive. The frequency of the air removal test and other sterility monitoring tests should be based on QRM principles and tailored to each specific unit/line and steam supply system. For example, a daily frequency may be necessary for older systems while this frequency may not be necessary for modern well-maintained systems.

1200.1204	<p>In currently written, the section contains an example that may be misinterpreted as being prescriptive and/or unclear. In addition, as currently written the section can be misinterpreted as requiring positive pressure of all systems regardless of environment it is in or if it is a sealed system.</p>	<p>If it is necessary to use equipment or components using BFF (e.g. sterilization incubator) prior to the sterilization process, then a risk-based assessment should be conducted to demonstrate the acceptable design level that will not impact the sterility of the equipment utilized and the product sterility assurance level. the minimum amount of BFF should be applied (as per manufacturer's recommendations). The hold time between the warming phase and sterilization and the hold time between sterilization and use should be justified based on risk assessment and validated to demonstrate the absence of impact on the sterility of the equipment and on the product sterility assurance level.</p>	<p>The proposed change removes "sterilization incubator" to avoid any unintended limitations in allowable technology, by the use of an example. The proposed change also removes the language referring to using a risk assessment to demonstrate acceptable design in regard to sterility assurance, because as currently written the section may be misinterpreted as allowing companies to ONLY perform a risk assessment to justify sterility assurance risk. Instead, it would be more useful to have the reader focus on the key risk posed by wet materials, which is contamination generated during a prolonged hold time, and risk of re-contamination after sterilization for wet material, by setting the quantity of BFF to be used and the actual holding times confirmed through a validation.</p>
1201.1205	<p>In currently written, the section includes examples that may be misinterpreted as being prescriptive and/or unclear. In addition, as currently written the section can be misinterpreted as requiring positive pressure of all systems regardless of environment it is in or if it is a sealed system.</p>	<p>When steam in place systems are used (e.g. the final product, vessels and lyophilizer chambers), the system should be appropriately designed and validated to ensure all parts of the system are subjected to the required treatment. The system should be monitored the temperature, pressure and time at appropriate locations during routine use to ensure all areas are effectively and reproducibly monitored. These locations should be demonstrated as being representative of, and correlated with, the chosen to heat locations during initial and routine validation. Once a system has been validated by steam in place, it should remain integral and where design and operation requires, hold under positive pressure prior to use.</p>	<p>The examples have been removed from the first sentence, because the use of the examples may be misinterpreted as setting requirements that are not limits. Alternative or additional aspects of steam in place design are not beneficial. In addition, "where design, location, and operation requires" has been added to the first sentence, because some processes may not require and some systems may not be designed to be held under positive pressure. Where an benefit is gained from a system held under positive pressure, there should be no requirement for positive pressure, as the requirement may add complexity to meet the system's design. In addition, it is not always/realistic possible to monitor these critical locations (monitoring locations) are representative with the chosen to heat locations in a SIP system. Often the chosen to heat locations are first identified in connection with initial and/or routine validation. In addition, a requirement to hold steam in place sterilized lyophilizer chambers is particularly non-beneficial, because positive pressure are already in place to confirm chamber integrity after steam sterilization. There is a leak rate or drug vacuum which ensure the integrity of the chamber up to the start of the loading process. How positive pressure would not be necessary prior to the start of production and once loading begins, positive pressure would not be feasible. In addition, language should allow describing the different systems, including single use.</p>

1206, 1208	<p>In currently written, this section focuses exclusively on the achievement of temperature in the load which is insufficient to ensure sterilization efficacy. Sterilization efficacy can only be ensured through the achievement of time and temperature and/or PH in the load. Additionally, not all sterilizers contain real-time temperature monitoring positions. In these cases, it is important to combine the temperature and time from monitoring locations on the overall heat history of the product load.</p>	<p>For the qualification of accelerated steam sterilizers systems, it should be demonstrated that all parts of the load meet the minimum required time/temperature or minimum required PH and that routine monitoring probes are located in positions correlated with the product load heat history or in worst case positions identified during the qualification process.</p>	<p>The section has been amended to indicate that the qualification of accelerated steam sterilizers requires documentation that a minimum heat history (time at temperature or Physical Linking (PH) is met for the product load. The achievement of a minimum temperature without an associated time of exposure is meaningless in the qualification of steam heat sterilization process efficacy. Not all steam heat sterilizers contain consistent and upgradeable worst case positions/locations that can be utilized for routine probe monitoring and control locations. In these situations, monitoring and controlling probes are located in reference positions to which the product load heat history is correlated during the development and qualification of the steam heat sterilization process.</p>
2024	<p>In currently written, this section may be misinterpreted to require that devices meeting the critical space during a controlled intervention be immediately monitored for stable communication.</p>	<p>Revised gloves (and any part of the gown exposed to gown) is a risk to patient sterility that may potentially have direct impact on the patient sterility (e.g. the sterility of these areas is critical) may should be monitored for stable communication after critical operations and in case from the cleanroom. Other sections of the gown should be monitored on exit from the cleanroom at the end of an operation.</p>	<p>The example of devices has been removed and QRM language has been modified and added to clarify that the intent of the section is not to require operators gown monitored after interventions. This monitoring would require the operators to leave the cleanroom and re-gown prior to re-entry. Re-entry entering the operators from aseptic processing activities is disruptive and not necessary for all interventions, including different interventions and many corrective interventions, the devices do not should be risk based. In addition, the wording related to end of the gown monitoring has been clarified to be consistent with glove monitoring.</p>

2008.2064	<p>In currently written this section can be misinterpreted and generate more reliance on aseptic process simulations as the primary or sole means to validate the aseptic process and various aspects surrounding the aseptic process.</p>	<p>Proactive verification of the effectiveness of the controls in place for aseptic processing should include a process simulation not using a sterile medium media and/or surrogate in place of the product. The process simulation should not be considered as the primary means to validate the aseptic process or aspects of the aseptic process. The effectiveness of the aseptic process identifies/determines through process design, adherence to quality system and process controls, training, and evaluation of monitoring data. Selection of an appropriate medium media and/or surrogate should be made based on the ability of the media and/or surrogate to isolate physical product characteristics ensured to pose a risk to product sterility during the aseptic process at all processing steps. Where processing steps may adversely impact the stability of any inoculated microbial contamination, (e.g. sterile aseptically produced semi-solid, gels, solid materials, micropheres, liposomes and other formulations where product is cooled or heated or lyophilized), alternative procedures that represent the operations as clearly as possible can be developed and justified. Where surrogate materials, such as buffers, are used in parts of the process simulation, the surrogate material should not inhibit the growth of any potential contamination.</p>	<p>Sections 9.34 and 9.40 provide a good opportunity to improve aseptic process control by emphasizing further prevention through process understanding, design and evaluation, rather than through detection and testing. In section 9.34, the first proposed change adds one sentence written to avoid the over-reliance on aseptic process simulations as the primary or sole means to validate the aseptic process and aspects of the aseptic process, including personnel performance, interventions, equipment suitability, product and material hold times, and environmental cleanliness. The sentence reinforces that while aseptic process simulations may be useful in assessing weakness or under-addressed variables in the process, it is not sensitive enough to validate the performance of a cleanroom process, the effect of personnel behavior on the process, the effectiveness of controls, the effect of environmental response, or the design and condition of equipment. The sentence is added to demand companies that merely performing aseptic process simulations, rather than relying on more important means to ensure control of the aseptic process, including proper process design, contamination control strategy, training, and process understanding. This misunderstanding has led to more confidence in less than optimal processes and the acceptance of improper process activities. The second proposed change to section 9.40 adds risk assessment language in place of the word "all product characteristics". The change clarifies and emphasizes the need to take into consideration those characteristics of the product that pose a risk or have an effect on the performance of the aseptic process rather than all product characteristics, some of which have no impact on product sterility during the aseptic process. Companies should evaluate their product on a risk basis and make and be prepared to defend decisions in accordance with those assessments. Building on the points made in section 9.34, the examples in section 9.40 have been replaced with risk assessment language and the word "validation" has been added to reinforce the need for companies to evaluate and include any aspects of the process that pose a risk to product sterility, rather than only focus on the items listed in the example.</p>
2008.2070	<p>In currently written, the examples in the section may be misinterpreted as being prescriptive and exclusive. In addition, clarification is needed for the categorization of skills and operators included in the IPR. In addition, the performing IPR was before decisions may not be beneficial.</p>	<p>Process simulation tests should be performed as part of the initial validation, with at least three consecutive satisfactory simulation tests that cover all testing skills that the aseptic process may occur in, and after any significant modification to operational practices, facilities, utilities, equipment which are assured to have an impact on the sterility assurance of the process and product sterility, or equipment (e.g. modification to the IPQC system, equipment, major facility that does, change to process, number of skills and number of personnel, etc.). Monthly, process simulation tests (specific verifications) should be repeated using a pure (representative) every six months for each aseptic process, each filling line and each working skill. Each qualified operator should participate in at least one successful IPR annually. Consideration should be given to performing an IPR after the first batch prior to that date, before long periods of inactivity or before decommissioning or relocation of a line.</p>	<p>Building on the points made in section 9.34, the examples in section 9.40 have been replaced with risk assessment language to reinforce the need for companies to evaluate and include any aspects of the process that pose a risk to product sterility, rather than only focus on the items listed in the example. The second proposed change to section 9.40 replaces "operator" with "qualified operator" and "skills" with "working skills" to clarify and align with other text in the chapter. The third proposed change to section 9.40 change eliminates the requirement for performing process simulations before a date date or decommissioning. The change is meant to emphasize that companies should have contamination control strategies that provide confidence and assurance of product sterility for every batch and every day that the process is commercially performed, as mentioned in the proposed change to section 9.34. It is important that companies understand that confidence should be based on proper process and Quality System design, process performance, and training, rather than on passing a media fill. If the process and the control strategy have been properly designed, performed, and maintained, then there should be confidence that the product manufactured by that process maintains quality attributes up to the time the process is stopped. When the process and control strategy does not provide that confidence, then the process inadequacies must be addressed before the process is performed. The passing of media fills does not replace that need. To the contrary, it will result in a false sense of confidence and dissuade companies from relying on prevention through proper process design and control, rather than a reliance on testing.</p>

<p>2020-2024</p>	<p>In currently written, the review may be misinterpreted as requiring complete visual inspection training and on-ops for people inspecting media filled units. In addition, as currently written, the review requires growth promotion tests (GPT) using local isolates, which may not be scientifically beneficial.</p>	<p>On completion of incubation:</p> <ol style="list-style-type: none"> 1. Filtered AFB₁ units should be inspected by staff, who have been appropriately trained and qualified for the detection of microbiological contamination in the visual inspection procedure, under conditions similar to those for visual inspection. Inspection should be conducted under conditions that facilitate the identification of any microbial contamination. 2. Samples of these units should undergo positive control by incubation with a suitable range of reference organisms, and local isolates. 	<p>The wording in sub-section 1 addressing more general visual inspection training and conditions has been replaced with microbiological contamination related wording to clarify the intent of the sub-section. Local isolates has been removed from sub-section 1, because the purpose of performing GPT following the incubation period of a media fill is not to demonstrate the media has acceptable growth promoting properties, which is established during incoming QC testing, but to demonstrate that the media has not been compromised during the preparation and sterilisation (i.e. increases filamentation, excessive leaching, prolonged storage under unfavorable conditions, etc.) and there were no residual cleaning agents or product residues remaining in the system that could have interacted with the media and rendered it unfavorable for growth promotion during incubation.</p> <p>Locally increased microbial environmental isolates (EI) are not standardized cultures that remain consistent and compatible between areas and laboratories. Unlike the QC microorganisms cited by the various compendia to be used for GPT and suitability testing, these isolated and held as an EI culture in the microbiology laboratory any specific phenotypic traits could be lost or changed during its maintenance in a high nutrient media.</p> <p>Supplemental information and references:</p> <p>The use of local microbiological isolates for performing gas media fill incubation growth promotion testing is unacceptable based on the published scientific evidence listed below:</p> <ul style="list-style-type: none"> • There is experimental proof of genetic alteration. Adaptation of environmental bacteria to laboratory conditions can lead to modification of important traits, that has been termed domestication (1). These authors note that "four-week isolated strains of E. coli showed changes in metabolism, morphology, and fitness", in addition, "the domestication changes are not uniform across a species or even within a single domestication population". The laboratory liquid or solid media environments during storage has also been documented during the domestication effects (1). • In research by Jan Benzek, et al., (2018), their report confirms the phenomena of "domestication of industrial microbes". They proved that during the domestication process, microbes gained the capacity to efficiently consume petri-dish nutrients, cope with a multitude of industry specific stress factors, when at the cost of a reduction in fitness in their original, natural environments. In, in time, during laboratory storage making them less representative of their original environments, which they are falsely designed to represent during the GPT (2). • Bacteria evolve rapidly not only by mutation and rapid multiplication, but also by transformation by naked DNA uptake and recombination but also with plasmid acquisition via the Conjugation process under natural conditions. These acquired mutations be stored or lost during artificial laboratory sub-culturing when the selective pressure that induce their expression are no longer available. The loss of an EI unique plasmid during laboratory storage would render the isolate non-representative of the source environment (3). • Collaborating evidence was published by Bin Lin, et al., (2017) that documented the effects on four strains of E. coli, that exhibited up to 20 mutations in all cultures of natural isolates within 10 days of transfer to rich media or with a single growth cycle involving an extended stationary phase (4). <p>References:</p> <ol style="list-style-type: none"> 1. <p>3.3. Other significant comments</p>			
<p>Overall</p>	<p>Throughout our comments on the Annex 1 review, we have recommended the removal of specific examples. However, as a general recommendation, we urge the authors consider removing the examples, where these examples may result in misinterpretation of intent of the Annex review.</p>	<p>Removal of examples.</p>	<p>Numerous sections throughout the 2020 revision, version of Annex 1 cite an include examples. These examples which are noted in parentheses, or with the construction of e.g., for example, such as, etc. The members have requested that the use of examples may be and often are misinterpreted by the reader of the Annex and by some inspectors as the prescriptive or exclusive intent and expectation of the EMA. While we understand that this is not the intent of the Annex 1 authors, this misinterpretation can result in unintended negative consequences, including:</p> <ul style="list-style-type: none"> ... discouraging companies from considering or using new, innovative, and beneficial alternative approaches, because these approaches are not stated by or aligned with the positions noted in the examples, ... discouraging companies from using risk based decisions to develop new beneficial approaches, ... companies opting to use approaches that may add unnecessary burden and take away resources needed to the more beneficial efforts, ... companies adopting the example without adequate assessment, justification, validation to support the suitability of their values or way of working to their process, assuming instead that if they merely following the example will be sufficient for process control.

Overall	<p>Both groups and endonyms are used throughout the 2020 revision, sometimes appearing to be used interchangeably and sometimes redundantly. While the words denote similar entities, they are not always interchangeable and may involve different control and detection methods. In many cases, the term <i>progeny</i> is encompassing, and where this is the case, we recommend sole use of that term.</p>	<p>Use of “progeny” and “endonyms.”</p>	<p>It is important to recognize that not all parental groups are bacterial endonyms. Historically, parental groups usually due to non-endonymic groups have occurred (e.g. population or geographical subdivision of <i>Salmonella enteritidis</i>) and the parental for non-endonymic groups nomenclature remains valid. Throughout the 2020 revision the terms <i>progeny</i>, <i>progeny</i> or <i>progenies</i> are mentioned 18 times. The terms <i>endonyms</i> and <i>endonymic</i> are used nine times. For the most part the usage of the term <i>progeny</i> and its related singular variants the usage of the term <i>endonyms</i> is appropriate, but there are a limited number of places where the wording can be simplified and maintain consistent use of the most scientifically correct term of <i>progeny</i>. To ensure consistency and fidelity to accurate science the term the decision on which term is most scientifically accurate should be made and justified as part of the CCN development.</p> <p>Specific references to these sections are noted in an appendix to our comments.</p>
Overall	<p>We continue to advocate for the replacement of traditional terms that may not be technically correct, with more scientifically accurate terms. To this end, we recommend that the authors use the opportunity for Annex 1 revision to replace the industry as the need to replace the phrase “non-viable particulates” with “total particulates”.</p>	<p>Use of “total particulates” rather than “non-viable.”</p>	<p>As discussed broadly at FDA workshops, conferences and meetings, non-viable particulates may be interpreted as indicating that the particles have no microbiological properties and are therefore not sources of contamination. Thus, of course, is not always the case. Total particulates more accurately describes what should be monitored and presents a clearer means and basis for control.</p>

Overall	<p>The 2009 Annex I represents an improvement over the 2007 version in that it largely stresses Alert Levels, rather than Alert Limits, because Alert Levels is a more conservative term.</p> <p>However, the continued use of Limits in general and Action Limits in particular, should be minimized and also replaced with Levels, as noted in the 2009 recommendations.</p>	Use of "levels" rather than "limits"	<p>Since 2008, the importance of the recommendation has been reinforced during IRIIA industry meetings and conferences related to Annex I revisions. These meetings showed that the industry was making progress in understanding the benefits of analyzing data and trends, rather than reacting to excursions from prescribed limits. This recognition of the importance of analysis of trends will allow companies to recognize problems before they reach a level of failure, thus improving process performance and reducing risk to product quality.</p> <p>For this reason, we continue to advocate for the use of Levels rather than Limits. As stated in 2008, "Levels denotes an analysis of trends, providing useful information to make informed, sound risk based decisions, as no failure is the overall intent of the revision. Limits denotes an absolute threshold that may never be crossed, not allowing for such risk based decision making. Action and alert levels should be risk based, accounting for the chemistry/process design, technology employed, and historical study trends."</p>
Overall	<p>Where applicable, the guidance, recommendations and requirements presented in the Annex should be consistent with recognized IRII standards, such as those presented in the IRII IRIIA notes.</p>	Consistency related topics should be consistent with IRII standards	<p>Throughout the 2009 Annex I revision, cross cross design, classification, qualifications, operations and monitoring are discussed. Where applicable, the guidance, recommendations and requirements presented in the Annex should be consistent with recognized IRII standards, such as those presented in the IRII IRIIA notes. This consistency is important, because it will reduce confusion and misinterpretation of the regulatory expectations regarding industry guidance, consensus standards, and current regulatory requirements.</p>
Overall	<p>In some cases, the revision is not distinguish between different requirements for terminal purification and aseptic processing. How the apparent lack of differentiation will lead to misapplication of control strategies where there may not be an issue or benefit, including conditions addressing media filter verification, media testing, and equipment verification.</p>	Clear distinction should be made between requirements for aseptic processing and terminal purification.	<p>Most of the revisions in the Annex primarily apply to aseptic processing. While many of these revisions are also applicable to terminal purification, several requirements are either not applicable, unnecessary, or not feasible when applied to terminal purification. Throughout the Annex we attempted to identify and offer recommendations. In these cases, it is important that clear distinctions are made between respective requirements.</p>

R26.026	<p>In currently written, the section may be misinterpreted as requiring the creation of disinfectants, thus requiring clarity on the criteria for the evaluation of the effectiveness of a disinfection program and the need to individually assess all the parameters which contribute to it.</p>	<p>The distribution of disinfectants is particularly important. They should be cleaned and distributed thoroughly in accordance with a written programme. The distribution to be effective, prior cleaning to ensure surface contamination should be performed. Cleaning programs should effectively remove disinfectant residues.</p> <p>Other than one type of disinfecting agent should be employed to ensure that where they have different modes of action and their combined usage is effective against all bacteria and fungi. Disinfection should include the periodic use of a sporicidal agent. Monitoring should be undertaken regularly in order to assess the effectiveness of the disinfection program and to detect changes in types of microbial flora (e.g. organisms resistant to the disinfectant regime currently in use). Where monitoring results show that the disinfection programme is not effective an investigation should determine the reason for (i) not adequate disinfectant frequency or disinfectant mode of action or disinfectant application/concentration...; and corrective actions should be implemented Cleaning programs should effectively remove disinfectant residues.</p>	<p>Language has been added to reinforce the importance of a well planned and qualified distribution programme. Language has been changed that indicates that the statement may be effective against all bacteria and fungi (as this is not achievable), and that a rotation of disinfectants is necessary, in addition to the use of a sporicidal agent. "More than one type of disinfecting agent should be employed" appears to recommend to require the rotation of disinfectants with different antimicrobial agents. In addition, the effectiveness of the disinfection programme is not always due to the mode of action of the disinfectant, all factors need to be considered, including e.g. disinfectant concentration, disinfectant frequency, etc.</p> <p>Additional reference material:</p> <p>This position is stated in technical papers and the aseptic processing point to consider, as well as scientific literature (e.g. <i>Alers and Agellous PDA, J Pharm Sci and Tech 2000</i>; Volky G, Kaehjeng, Lene Glum, International Journal of Food Microbiology 100 (2002) 11-15, and H. Maitani, Pharmaceutical Technology (Feb 2, 2009) PDA TR-76, USP <1072>) suggests that many companies would not adopt no disinfectants (in contrast to antibiotic resistance). PDA report No. 70 notes that the pharmaceutical industry is moving away from rotation of disinfecting agents since it leads to higher residue levels, without material benefit. Carol Inneson, PDA TR-76 Fundamentals of cleaning and disinfection programs for aseptic manufacturing facilities 2010; Alers, J. Agellous, Environmental Monitoring: Myths and Misapplications PDA, J Pharm Sci and Tech 2001, 31 176-184; Volky G, Kaehjeng, Lene Glum, International Journal of Food Microbiology 100 (2002) 11-15, Industrial disinfectants do not always for resistance in Listeria monocytogenes following long term exposure; and H. Maitani, Pharmaceutical Technology (Feb 2, 2009) The Rotation of Disinfectants Principle. Year in Review USP 40 NF 15, chapter <1072> Disinfectants and sanitizers; PDA Points to Consider for Aseptic Processing Part 2 (2004)</p>
R27.074	<p>In currently written, the section may be misinterpreted as pertaining to terminal sterilization as well as aseptic processing. In addition, as currently written, the section may be misinterpreted as requiring the modification of equipment that contact surfaces, or aseptic components that do not contact sterile product, i.e. the creation of viable. In addition, as currently written, the section can be interpreted as limiting modification to traditional methods that are not well suited the transfer of large equipment into isolators.</p>	<p>Direct and indirect contact parts used for aseptic processing should be sterilized. Direct contact parts are those that the sterile product passes through, such as filling needles or pumps. Indirect contact parts are equipment parts that come into contact with sterilized critical items and components the surface of critical items and components that contact sterile product. Where indirect product contact equipment design does not allow for heat sterilization and installation, a risk assessment should address the use and control required the alternative methods to address product sterility.</p>	<p>"Used for aseptic processing" has been added to the first sentence to clarify that the requirement for sterilization pertains only to aseptic processing and not terminal sterilization. Sterilization of these parts is unnecessary and has not been a requirement for terminally sterilized parts products in the past. For this reason, it is recommended to relocate this section to Part B of the Annex "Aseptic preparation and processing". "Surface of" and "that contact sterile product" have been added to the second sentence to clarify that the intent of the section is to require modification of components and parts that contact the surface of sterile containers. In addition, a warning has been added to the end of the section to clarify an allowance for alternative sterilization methods or combinations of methods. This is important, because since the 2017 version of Annex 1 was prepared there have been concerns expressed to the PDA from members that the Annex should allow for the pre-assembly and in place sterilization of large, component handling equipment. Our concern is that without such options, companies may be dissuaded from using innovative isolator designs that are more compact and less risky, or companies may try to use obsolete techniques for large sterilized equipment, that are not well suited to these isolator designs. We recognize that in-place sterilization methods may be complex and if not performed correctly may not be effective. However, any sterilization method proposed by a company should be properly validated and if so, should be allowed.</p>

888.892	Generally as written this section may potentially be too prescriptive and may not align with applicable recommendations or standard language the certain instrumentation.	Particle counters, including sampling tubing, should be qualified. The tubing length should be no greater than 1 meter with a maximum number of bends and local radii should be greater than 18 cm. The parameters of the complete sampling system (including tubing length, diameter, radii, probe size, number of bends) should comply with the manufacturer's recommendation for the particle counter selected. Portable particle counters with a stem length of sample tubing should be used for classification purposes. Inhalation sampling heads should be used in multidirectional airflow systems. A sampling probe should be selected to permit clear unobstructed sampling in areas with multidirectional flow and should be positioned as close as possible to sample an representative of the critical location.	The use of prescriptive values for the length and bend radius may hamper the use of different methods, needed to support new manufacturing technologies, or it may allow values that are not optimal. We recommend the user only use follow the instrument manufacturer recommendations upon IEC 60604. This will not preclude the use of different parameters in the particle counter technology evolves. The wording in the last line in the section has been changed to align with ISO 60604 language for particles $\geq 0.3\mu m$ but is still applicable for particles $\geq 0.3\mu m$.
744.744	As currently written the section may be misinterpreted as preventing the use of the AER to validate the number of people allowed in the classroom.	Only the minimum number of personnel required should be present in classrooms. The number of operators required should be determined during process design. The maximum number of operators in classrooms once determined should be, determined and validated during activities such as initial qualification and aseptic process simulations, as well as competency testing exercises. This is particularly important during aseptic processing.	Those using the guidance should understand that the impact of the presence and behavior of people in the classroom involve variables that cannot be validated as one would validate other process parameters. The AER is more designed to ensure process variables are identified or adequately controlled in process design. It along with classroom qualification work are not sufficient enough to determine the acceptability or an acceptable number of people. As currently written, the section may be misinterpreted as doing such, thus preventing a fair sense of confidence that demands other more effective efforts to design a process that minimizes the number of people required. In addition, the number of persons should be determined prior to the qualification or validation studies, rather than during the studies. The proposed changes clarify the intent of the guidance without removing the concern.
754.754	The section as currently written disqualifies all personnel who participated in any part of a failed AER.	There should be systems in place for disqualification of personnel from working in or supporting any into classrooms based on events including ongoing assessment and/or identification of an adverse event from the personnel monitoring program and/or after participation in a failed AER, where the failure is attributed to that person's aseptic technique or behavior. Once disqualified, retraining and requalification should be completed before permitting the operators to have any further involvement in aseptic practices. For operators entering Grade B environments or performing intervention into Grade A areas, this requalification should include demonstration of participation in a successful AER.	Wording has been added to clarify that where an AER fails as a result of cause unrelated to the aseptic technique or behavior of a person, that person or persons should not be disqualified from working in the clean rooms. Notwithstanding, the disqualified person may still be allowed back into the classroom to participate in the "requalification" AER.

E05.006	<p>The section is currently written, may be misinterpreted as requiring a procedure for the line testing of sterile zones at time of use.</p>	<p>The clothing and its quality should be appropriate for the process and the grade of the working area. It should be worn in such a way as to protect the product from contamination. Where the type of clothing chosen needs to provide the operator protection from the product, it should not compromise the protection of the product from contamination. Garments should be visually checked for cleanliness and integrity immediately prior to gowning and prior to entry to the cleanroom. Once integrity should also be checked upon exit. For certified or effectively decontaminated garments and eye coverings, particular attention should be taken to ensure they have been processed, are within their qualified hold time and that the packaging is visually inspected to ensure it is intact before use. Reusable garments (including eye coverings) should be replaced if damage is identified or as a use frequency that is determined during qualification studies. Damage to garments may not be identified by visual inspection alone, so the qualification should consider any necessary garment testing requirements. The qualification of garments should consider any necessary garment testing requirements, including damage to garments that may not be identified by visual inspection alone.</p>	<p>The proposed change explains the section to clarify that damage should be considered as part of the initial qualification of the garments, while making it clear that more qualified, visual inspection of the garments (as noted in the second sentence) is regarded as sufficient.</p>
E14.009	<p>The section is currently written, may be misinterpreted as encouraging excessive movement of cold and remaining in the cleanroom if moving excessively. In addition, the prevention of shivering may not be feasible.</p>	<p>Clothing should be chosen to limit prevent shivering due to operators increased excessive (when cold) or sweating (when hot).</p>	<p>Cleanroom clothing is not single and therefore does not prevent shivering, instead it limits shivering. Excessive movements when feeling cold or when sweating should be prevented in cleanrooms, because of excessive prevents shivering.</p>
E09.006	<p>Suggested removal of the requirement for the mandatory use of Grade C environments for all products that actively support microbial growth. A comprehensive risk assessment should be made that can lead to different and more suitable approaches to ensure the sterility of the terminally sterilized product.</p>	<p>Preparation of components and materials should be performed in at least a Grade D environment in order to limit the risk of microbial, pyrogen and particulate contamination, so that the product is suitable for sterilization. Where the product is at a high or unusual risk of microbial contamination (e.g. the product actively supports microbial growth, the product must be held for long periods before filling or the product is not processed aseptically in closed vessels), then preparation should be carried out in a Grade C environment. Preparation of solutions, creams, suspensions and emulsions should be carried out in a Grade C environment before terminal sterilization.</p>	<p>The contamination control strategy must be based on comprehensive QRM which takes into account all different elements that contribute to the sterility assurance of the process and sterility of the product. Not relying upon the cleanliness grade of the manufacturing environment may give an incorrect sense of security and prevent to address other equally important or even more important elements that contribute to the product sterility. For example, many operators drug formulations actively support the growth of microorganisms, but proper validation of the unit to sterilization time limits and processing aseptically in closed vessels can be utilized to effectively mitigate this risk without the requirement of a Grade C environment. Specifically, with processing aseptically in closed vessels, there is a very limited level of exposure of the product to the mixing room environment which also supports the use of a Grade D environment for this operation. The requirement for the use of a Grade C environment for all products that actively support microbial growth represents an unnecessary burden on industry and provides negligible mitigation of risk to the assurance of product sterility.</p>

894.897	As currently written, the examples used in the section may be misinterpreted as being the prescribed or exclusive conditions for a requirement that may not always be necessary or beneficial in these stated conditions.	When the product is sealed or gassed an unusual risk of contamination from the environment, because, for example, the filling operation is slow, the containers are wide necked or are necessarily exposed for more than a few seconds before closing, then the product should be filled in a Grade A room with at least a Grade C background.	The examples have been removed from the section and replaced with QRM based wording. However all of the highlighted examples listed the applicability of this term do not necessarily represent a high or unusual risk of microbial contamination that could impact the assurance of sterility for essentially sterile final products. Perhaps, it can be demonstrated that a Grade C environment and associated microbiological control practices result in a level of product bioburden that represents a very low challenge when compared to the challenge level of the biological indicators utilized to develop and qualify a terminal sterile heat sterilization process. The requirement for the use of a Grade C environment for any of the filling conditions stated represents an unnecessary burden on industry and prevents equitable mitigation of risks to the assurance of product sterility.
1199.1199	As currently written, the example used in the section may be misinterpreted as being the prescribed or exclusive method, thus limiting the use of modern or innovative technologies.	Each heat sterilization cycle should be recorded either electronically or by hardcopy, on equipment with suitable accuracy and precision. Monitoring and recording systems should be independent of the controlling system (e.g. by the use of digitalizable probes) to have redundancy and/or redundancy to detect a cycle not conforming to the validated cycle parameter requirements and also to fail this cycle.	The example has been replaced with broader language, because the representation of a modern sterilization process should be a Quality by Design (QbD) approach which identifies all parameters, phases, times, etc., that are critical to a successful sterilization cycle. The design of the system should have a control strategy such that alarms and controls are in place that detect and alert a cycle that deviates from the validated cycle. This enables the use of automation (digital plant) to identify a cycle not meeting the parameters versus manual review. Independent probes could be a way to confirm that the entire cycle is in conformance with the validated cycle but are not the only way to do this. Identifying a non-conforming cycle can be accomplished through multiple (redundant) monitoring (temperature, pressure, liquid volume in drain, etc.) as well as comparisons of temperature and pressure against the estimated steam curves that ensure a successful cycle (overheating double temperature probes). The proposed modification sets this QbD expectation to identify the parameters system and ensures that the proper safeguards are in place to detect and alert a cycle not meeting a valid cycle. If the change is not accepted, request at least the acknowledgment in the requirement that a QbD approach to accomplish this is possible to allow technology to support these processes as much of industry is working to leverage digital plant, AI and other advanced systems to move away from manual systems of sterilization systems.
1194.1197	As currently written, the section may be misinterpreted as being applicable to all sterilization loads, while the requirement is relevant for process heat loads only.	The position of the temperature probes used for controlling and/or recording should be determined during and on going to the validation which should include heat distribution and penetration studies and, where applicable, also checked against a second independent temperature probe located at the same position.	‘‘Ongoing’’ has been replaced with ‘‘on going’’ to clarify that key process operating parameters including the positioning of monitoring probes should be known and in place for the validation study, rather than determined as a variable during the study.
1199.1200	As currently written, the section may be misinterpreted as being applicable to all sterilization loads, while the requirement is relevant for process heat loads only.	The process heat loads load. Sufficient time should be allowed for the whole of the load to reach the required temperature before commencement of the sterilizing time period starts. For sterilization cycles controlled using a reference probe within the load, specific consideration should be given to ensuring the load probe temperature is controlled within defined temperature range prior to cycle commencement.	The process heat loads load has been added to the beginning of the section to clarify intent of the section. The requirement for the whole of the load to reach the required temperature before initiation of the sterilizing time period represents a requirement for load equilibration which is only applicable to process heat loads. With liquid loads, solution formulations may include probes fill volumes of up to 5 liters which results in a considerable lag in temperature of the load behind the temperature in the medium. Therefore, temperature equilibration prior to the start of the sterilizing phase is not applicable for liquid loads as long as it has been demonstrated that minimum physical (PI) and biological lethality requirements for the sterilization process are reliably met.

1290.1290	Although recognized as separate processes, a currently written section 8.07 does not separate the requirements for dry heat sterilization and decontamination.	Dry heat sterilization utilizes high temperatures of air or gas to sterilize a product or article . In its particular use in the removal of thermally stable contaminants such as pyrogen and is often used in the preparation of components for aseptic filling. The combination of time and temperature to which product, components and equipment are exposed should produce an adequate and reproducible level of lethality and/or pyrogen (endotoxin) inactivation/removed when operated routinely within the established limits. Dry heat sterilization is often conducted with of particular use in the thermal removal of difficult to eliminate thermally stable contaminants such as pyrogen , and is often used in the preparation of components for aseptic filling. The combination of time and temperature to which product, components and/or equipment are exposed should produce an adequate and reproducible level of lethality and/or pyrogen (endotoxin) inactivation/removed when operated routinely within the established limits.	The proposed change to section 8.07 clearly the intent of the section by separating the requirements for sterilization and decontamination into two sets of sentences.
1290.1300	As currently written, section 8.07 can be misinterpreted as requiring that air flow visualization studies be carried out in the dry heat/decontamination tunnel.	Dry heat sterilization/decontamination tunnels should be configured to ensure that airflow patterns, the integrity and performance of the Grade A sterilizing zone by maintaining pressure differentials, and airflow through the tunnel from the higher grade area to the lower grade area. Airflow patterns should be visualized and controlled with temperature studies. The impact of any airflow change should be assessed to ensure the heating profile is maintained. All air supplied to the tunnel should pass through at least a HEPA filter and periodic tests should be performed to demonstrate air filter integrity (as listed manually) at a frequency determined by QRM . Any tunnel parts that come into contact with sterilized components should be appropriately sanitized or disinfected. Critical process parameters that should be considered during validation and/or routine processing should include, but may not be limited to:	The change to section 8.07 clearly the intent of the section. Airflow visualization cannot be carried out in dry heat sterilization/decontamination tunnels. HEPA filter integrity testing should be based on QRM, using leak visualization monitoring (e.g. particulate count) and performance data, as well as the different testing environment / aging for the hot and cold zones, and the filter replacement plan. Airflow visualization through an air filter and under of dry heat sterilization/decontamination tunnels will provide no value beyond pressure differential and/or airflow velocity measurements.
1300.1320	As currently written, the section does not acknowledge that the decontamination is a combination of processes. In addition, as currently written, the section does not indicate that if decontamination conditions are met, it is not necessary to prove sterilization.	When a thermal process is used as part of the decontamination process is used for any component or product contact equipment, validation studies should be performed to demonstrate that the process provides a suitable D ₁₀ value and results in a minimum 7 log reduction in contamination concentration. When this is achieved, there is an additional requirement to demonstrate sterilization in other cases.	The final sentence has been changed to acknowledge that the decontamination process is a combination of washing/rinsing and thermal processes. It is important to recognize the role the non-thermal step(s) play in the overall decontamination process. In addition, a sentence has been added to the end of the section to indicate that where decontamination conditions are met, it is unnecessary to prove that sterilization conditions have been met, because the conditions for decontamination significantly exceed those for sterilization. Without this addition, the section may be mis interpreted as requiring additional and unnecessary validation studies.

1522-1526	As currently written, the section should be clarified that not all the critical process parameters listed are applicable to use of hermetically packed loads.	Dry heat ovens are typically employed to sterilize or dehydrate primary packaging components, finished materials or active substances but may be used for other processes. If the load is not hermetically packed, then the oven they should be maintained at a positive pressure relative to lower grade areas throughout the sterilization and post-sterilization hold periods. All air entering the oven should pass through a sterilizing filter. Critical process parameters that should be considered in qualification and/or routine processing should include, but may not be limited to: i. Temperature ii. Exposure period/time iii. Chamber pressure (the maintenance of zero pressure) - if applicable iv. Airflow velocity speed - if applicable v. Air quality within the oven - if applicable vi. Heat penetration of material article (slow release spore) vii. Heat distribution/uniformity.	For hermetically packed loads, such as used in API sterilization, the requirement to have a positive pressure during sterilization and during the cooling phase would not be necessary, due to the product protection by the packaging barrier. As a consequence, requirements (ii), iv) and v) are only valid as critical process parameters in certain other applications.
1526, 1527	The section as currently written would have the unintended consequence of excluding the use of absolute filtration as a method as part of a method.	Sterilization by radiation is used mainly for the sterilization of heat sensitive materials and products. Ultraviolet irradiation is not an acceptable method of sterilization.	Science on UV irradiation as a not acceptable sterilization method has been assessed, because while we agree that the current ultraviolet irradiation technology may not currently be an effective method for sterilization, improvements in the technology may make it a useful a viable sterilization modality in the future.
1527, 1529	As currently written, the section may be misinterpreted as requiring HEPA monitoring for governmentally released HEPA cycles.	Unless parametric release has been approved , each sterilization cycle should be monitored with suitable HEPA, using the appropriate number of test units distributed throughout the load at defined locations that have been determined to occur over during validation.	The requirement for the use of HEPA in this section prohibits the use of the most advanced practice of parametric release. Therefore, wording has been added to the section to clarify that HEPA cycles can be properly controlled via parametric control, based on technology, i.e. without HEPA, as per ICH Q11B:2016 old 2015 Section 11.1, D15.2.3, B10.5, and B10.6, which permits the release of HEPA-sterilized product without the use of HEPA.
1527, 1528	As currently written, the section requires clarification for redundant filtration.	Bibaculous samples should be taken from the bulk product and immediately prior to the final sterile filtration set-up. In cases where a redundant filtration setup is used, it should be taken prior to the first filter . Systems for taking samples should be designed so as not to introduce contamination.	Wording has been added to the section to address redundant filtration. In redundant filtration, each filter is validated to obtain a sterile filtrate, therefore the filtrate side of filter one should not be compromised. To determine the maximum allowable bioburden in line of the filtration system, the sample has to be taken in front of filter one, as the bioburden in front of filter one should be zero.

1608.1611	As currently written, the section may present requirements that cannot be met with existing equipment design.	The sterile eye equipment used for capsule filling, the one lever/piston capping and mould filling should be supplied with Grade A air quality to prevent this should be covered by a flow of filtered air to provide Grade A conditions at the critical zone. The equipment should be installed in at least a Grade C environment, provided that Grade A air clothing is used. The filling environment should meet Grade A for the table and associated lines at one end and the table line only when in operation.	Grade A 'condition' has been replaced with Grade A 'air supply', because it may not be feasible to demonstrate Grade A conditions at an active RPS sterile piston capping zone. The language inserted is consistent with another challenge posed by capping systems as noted in section 8.28 and should be adequate for contamination control.
1608.1618	As currently written, the section requires that the capability of the cession system to be validated to a level that may not be achievable.	Several parameters and microbial contamination of the polymer should be governed by appropriate design, control, and maintenance of the polymer storage, sampling and distribution system. The capability of the cession system to provide appropriate sterility assurance for the moulded container should be fully understood and validated. The sampling frequency, the techniques used, where applicable, endotoxin levels of the raw polymer should be defined and controlled within the OER.	'Fully' has been removed from the opening sentence, because it is an absolute term, and while a good objective, would be impossible to demonstrate in relation to sterility assurance. The overall system levels, times, and dispense and method plastic rate. In relation to sterility assurance relative to the exposure of the article to critical conditions during the cession process. However, because it is not possible to predict which unit is exposed to heat for a given length of time, it may not be feasible to achieve time and temperature exposure to the extent conditional required for heat neutralization.
1611.1613	As currently written, the section may be misinterpreted as requiring process validation studies be conducted for any change, regardless of the outcome of the risk assessment.	The modifications to form containers are considered critical equipment and any changes or modifications to moulds should result in an assessment of finished product container integrity and should be supported by validation based on the outcome of that assessment .	Risk based testing has been added to the end of the section to reinforce that some changes, for example changes to capping/moulding, would not necessarily pose a critical product container integrity and would not require validation.
1711.1711	As currently written, the section refers to intrinsic capsule containers, when intrinsic sterile containers would be more accurate.	It is critical to ensure the sterility of all product contact surfaces of closed systems used for capsule processing. The design and selection of any closed system used for capsule processing should ensure maintenance of sterility. Connection of sterile equipment (e.g. tubing / pipework) to the sterilized product pathway after the final sterilizing filter should be designed to be connected aseptically (e.g. by intrinsic aseptic sterile connections or isolation systems).	'Sterile' is replaced with 'sterile' in the example, because the section refers to connections that may involve closed systems as well as aseptic connections. In general, "intrinsic sterile containers" should be used consistently throughout the Annex for the purpose of connection of sterile equipment, including where used in Section 8.11, Line 170, Table 1, and Section 8.17, Line 1762.

1703, 1704	The section as written may be misinterpreted as requiring testing of each HIR unit upon receipt and prior to use.	Assessment of suppliers of disposable systems including verification is critical to the selection and use of these systems. The vendor HIR verification of sealing should be performed as part of the supplier qualification and no receipt testing of each unit.	Some points are already covered under 8.128. The reference to receipt and use of each unit has been removed. Because these units add more seal may be destructive, a misinterpretation of the intent of this section could have unintended negative consequences. The amended text is unnecessary, because Section 8.130, as currently written, already addresses the key requirements for HIR integrity. Reference 8.128 acceptance criteria should be established and implemented for HIR corresponding to the risks or criticality of the products and its process. On receipt, each piece of HIR should be checked to ensure that they have been manufactured, applied and delivered in accordance with the approved specification. A visual inspection of the outer packaging (e.g. appearance of exterior surface, product packaging (e.g. appearance of exterior surface, product packaging), label printing, and review of attached documents (e.g. certificate of conformance and proof of verification) should be carried out and documented prior to use.
1829, 1830	As currently written the section may be misinterpreted as requiring HIR data from less or non-critical areas be reviewed for batch release.	Reference: results from environmental monitoring should be considered when reviewing batch documentation for finished product batch certification	HIR data from critical grades, class A and B, should be reviewed and considered before batch certification, but review of HIR data from less critical grades e.g. class D should not replace the batch certification, unless evidence exists a need to evaluate the data from lower grades. Review of data should be QRM based. With satisfactory results from the evaluation of HIR data from class A and B there should be no need for including review of data from less critical areas as part of the batch certification. On the other hand, if challenges are seen in the grade A and B HIR results in relation to release of a batch then it might be relevant to also evaluate the results from lower grades.
1450, 1451	As currently written, the section may be misinterpreted as exclusively requiring those methods mentioned in the examples.	When sample operations are performed, the frequency, selection and combination of methods should be QRM based and include methods for surface, air, glove, and gown monitoring, as noted in Section 9.30 microbial monitoring should be frequent using a combination of methods such as swab plates, volumetric air sampling, glove, gown and surface sampling (e.g. swab and contact plates). The method of sampling used should be justified within the CCR and should be demonstrated across have a demonstrable impact on Grade A and B release patterns.	The examples have been removed from the section and replaced with QRM based language (linked to section 9.30) because as currently written, the use of examples may be misinterpreted as requiring prescriptive requirements. This could lead to a perceived requirement that methods such as swabbing gloves must be used in all releases, including gloveless and aseptic systems, where the changing of gloves involves intensive interventions that are detrimental to sterility assurance and may dilute companies from using these and other more advanced technologies in the future. The proposed change reduces the risk of this unintended consequence, without changing the intent of the section.
1453, 1454	As currently written, the section may be misinterpreted as requiring the duration monitoring of Grade B areas.	Continuous viable air monitoring in the Grade B area (e.g. air sampling in swab plates) should be undertaken for the full duration of critical processing including equipment (septic air sep) assembly and filling operations. The approach to monitoring of Grade B cleanrooms should be determined based on the risk of impact on the aseptic processing and its contribution of the product. The monitoring should be performed based on the determination of risk of aseptic processing including but not limited to, releases and connector interventions, medium errors, system deterioration, and risks caused by the intervention of the monitoring operations. The monitoring plan for Grade A and Grade B cleanrooms should be justified in the CCR.	The reference to Grade B areas has been replaced with QRM based language, because monitoring for the Grade B cleanroom should be determined using a QRM approach based on the overall risk to aseptic processing and to the product. The monitoring plan should consider all aseptic processing related risks including (should be provided as examples but not necessarily as exhaustive or comprehensive list) the interventions, medium errors, sources of system deterioration, and risks inherent to the monitoring operations employed.

<p>1998.1998</p>	<p>In currently written, this section could be re-integrated as existing companies qualify the overall recovery efficiency for sterile places, viable count air and surface monitoring by the user.</p>	<p>Sampling methods and equipment used should be fully understood and procedures should be in place for the correct operation and integration of results obtained. The recovery efficiency of the sampling method chosen should be qualified to confirm that sanitizing agents do not influence the recovery of microorganisms.</p>	<p>For viable air sampling these qualification studies are difficult to execute based on several reasons, including modification of recovery studies and recovery implications for the microbiology laboratory. The proposed change is aligned with the requirements stated in Annex 15 (Qualification and Validation) 9.3, and clarifies the intent of the section as focusing on the effect of sanitizing agents. Reference: Annex 15 (Qualification and Validation) 9.3. Where microbial testing of surfaces in clean rooms is carried out, validation should be performed on the system to confirm that sanitizing agents do not influence the recovery of microorganisms.</p>
<p>1998.2008</p>	<p>In currently written, the section was the term Action Limits, where Action Level would be more effective. In addition, as currently written, the suggested types of monitoring data reporting may be misinterpreted as the only permitted reporting format, thus limiting the use of existing or future alternative methods. In addition, as currently written, the section can be misinterpreted to require that germ monitoring results visible on growth.</p>	<p>Action limits levels for viable particle contamination are defined in Table 7 (range): a. Sterile places should be exposed for the duration of operations and changed as required after 4 hours (exposure time should be based on validation including recovery studies and it should not have any negative effect on the stability of the media used). Individual sterile places may be exposed for less than 4 hours. It should be noted that for Grade A, any growth should result in an investigation. However, certain alternative methods can not be growth based and may be reported as % v/v, no detection, or as another format. a. Contact plate limits apply to equipment and clean room and germ surfaces within the Grade A, zone and Grade B zone. Maximum germ monitoring levels should be defined and justified based on assessed risk posed to product sterility. Routine germ monitoring is not normally required for Grade C and D zones, depending on their function.</p>	<p>'Action limits' has been changed to 'Action levels', because levels denote an analysis of trends, providing useful information to make informed, sound risk-based decisions, as per Annex 15 to the overall intent of the section. Limits denote an absolute threshold that may serve as a control, not allowing for such risk-based decision making. Action levels should be risk based, accounting for cleanroom/process design, technology employed and historical study results. In addition, a note has been added to address the manner in which data be reported to allow the alternative methods, where data cannot be reported in terms of growth. In addition, germ monitoring has been reported from equipment and clean room surface monitoring, because it is impactful, reliable, and necessary for germ results to be maintained as no growth or very often (growth/prevalent) have been in the clean room for a length of time.</p>
<p>2014.2021</p>	<p>In currently written, the section may not allow for the use of rapid microbiological methods that do not allow for species level identification.</p>	<p>Microorganisms detected in Grade A zone and Grade B zone should be identified to species level and the potential impact of such microorganisms on product quality (to each batch/implication) and overall state of control should be evaluated. Consideration should also be given to the identification of microorganisms detected in Grade C and D zones (for example where action limits or alert levels are exceeded or where signals or potentially objectionable microorganisms are recovered). The approach to species identification and investigation should be documented. Where alternative rapid microbiology or other methods are used, which do not allow for speciation, the justification for using such methods should be made based on the benefits of these methods compared to the risk posed by limited identification capability.</p>	<p>ERM based language has been added to the end of the section to allow for alternative, rapid methods that might not provide species level identification. In this case, it may be more important to be able to see that on a lot rather than being able to do the identification. ERM gives the possibility of seeing that on a lot, which might be of higher importance than being able to do the identification.</p>

2008_2008	<p>In currently written, the sub-sections i, iv, and vi require clarification of measures more accurately reflect the intent of the section. Also, as currently written, sub-sections ii and vii may be interpreted as requiring a full cycle APS duration.</p>	<p>i. Process simulation tests should assess all aseptic operations performed subsequent to the sterilization and decontamination (decontamination cycle of essential unit) in the process or the point where the container is sealed.</p> <p>iv. Process requiring the addition of sterile products should use an acceptable surrogate material in containers similar to those used in the process under evaluation; the addition of sterile products should use an acceptable surrogate material in containers identical to those used in the process under evaluation.</p> <p>vi. The process simulation procedure the lyophilized product should represent the entire aseptic processing chain including filling, stoppage, loading, a representative portion of the chamber dwell, unloading and sealing under specified, documented and justified conditions representing worst case operating parameters.</p> <p>vii. The lyophilization process simulation should include duplicate all aspects of the process, except those that may affect the stability or recovery of contaminants. For instance, heating over or under freezing of the section should be avoided. Factors to consider in designing APS design include, where applicable:</p> <ul style="list-style-type: none"> - The use of air to break vacuum instead of nitrogen. - Replicating the maximum interval between sterilization of the lyophilizer and its use. - Replicating the maximum period of time between sterilization and lyophilization. - Quantitative aspects of worst case situations, e.g., loading the largest number of trays, replicating the longest duration of loading when the chamber is open to the environment. 	<p>'Decontamination cycle' has been replaced with 'sterilization' in sub-section i, because materials entering the critical zone are sterilized. Sub-section iv, has been modified to replace the difficulty to interpret "acceptable ..." with risk based language for selection of surrogate materials and containers. 'Identical' has been replaced with 'similar' in sub-section iv, because it would be impractical to demonstrate that containers are identical. 'Duplicate' has been replaced with 'simulate', in sub-section vii, because it would be impractical to demonstrate that all aspects of the process have been duplicated exactly. 'A representative portion of' has been added to 'chamber dwell' and the reference to replication of maximum time between sterilization and lyophilization has been removed in sub-section vi, because an APS duration of the entire cycle dwell could be multiple days, and this would be impractical and unnecessary.</p> <p>The third bullet point under sub-section vii, has been deleted, because it presents a requirement that may be impractical and unnecessary. The frequency for sterilization is combined to the overall risk of chamber contamination (e.g. during loading) as per point 8.111 and 8.102, and a modification process may be not necessary for multiple cycle for Lyophilizers loaded by automated closed systems or located within systems that exclude operator intervention - this is would be impractical to simulate each period of time (with intermediate lyophilization cycles) and not necessary provided that the aseptic chamber is processed from the external environment -</p>
2008_2008	<p>In currently written, the frequency of intervention inclusion is open to interpretation and misinterpretation.</p>	<p>i. Intervent and corrective interventions representative of the routine process performed in a manner similar to the manner in which they are performed during the routine aseptic process, at the maximum accepted frequency per number of filled units (e.g., loading of vials into a lyophilizer).</p> <p>ii. The inclusion and frequency of interventions in the APS should be based on a worst case guard to product sterility.</p> <p>iii. Corrective interventions, that occur infrequently during routine production, (in a representative number and with the highest degree of acceptable insertion (e.g., correcting potential support).</p>	<p>The language in the section has been revised to clarify the intent of the APS, because we understood the intent of the APS is to validate interventions or to show that a given frequency of interventions is acceptable. The inclusion of interventions in the APS is important because interventions are a part of the aseptic process that is being simulated. However, the APS is not sensitive enough to confirm or establish the acceptability of interventions. Instead, interventions are acceptable based on the design of the process in respect to line air and product exposure and the training of the people performing these interventions. Repeating interventions does not increase the risk of failure, nor the chances of occurring an improperly designed or performed intervention. Interventions are proper or not. Therefore, the number of times an intervention is required during an APS does not establish an acceptable limit for the frequency of the intervention. For inherent interventions, the correct number and frequency performed during the APS should be whatever the frequency is to maintain normal product rates during the period of the APS. For corrective interventions, the frequency should be assessed based on the value of the scientific information obtained from repeating the performance of the intervention.</p>

2017.0108	The above sub-sections have been changed to clarify the intent for such sections and reduce the risk of misinterpretation.	<p>iv. Minimums permitted/holding times for sterile product and associated sterile components and equipment required during the aseptic process.</p> <p>v. The method of detection of microbial contamination should be scientifically justified, to ensure that any contamination is detectable.</p> <p>ix. Where the manufacturer operates different or extended shifts, then the APS should be designed to capture specific fatigue profiles on those shifts that are assessed to pose a risk to product quality (e.g. for those manufacturing during a night or extended shift, fatigue should be considered). Because it is not possible to simulate human fatigue during an APS, where human fatigue is assessed to pose a risk to product quality, the process should be modified or designed to reduce the impact or risk of such fatigue.</p>	<p>In subsection iv, the reference to sterile components has been removed, because there would be not be practical to try to estimate or demonstrate the amount of time that individual trials would say as a variable or individual inputs would say in a test or happen. In theory, one or more of these components could be required for the entire production run or for a very small part of the run. In subsection v., the reference to creating that any contamination is detectable has been removed, because it is not possible to ensure that all or any contamination present in the clean room will be detected using standard media fills. In subsection ix., the reference to including fatigue as a factor in the APS has been removed and replaced with wording presenting a risk based approach, because, as understood (ii) it is not possible to simulate fatigue in an APS and (3) it is not always the case that night shift personnel would be any more susceptible to fatigue than day shift. However, where fatigue is judged to pose a significant risk, the process should be modified or designed to minimize the impact or risk of fatigue.</p>
2017.0128	As currently written, the section may be misinterpreted as requiring performance of multiple APS runs for manual operations that are not filling and stopping, which would be overly restrictive and burdensome for ATMP manufacturing.	<p>Where manual operation filling and/or stopping occurs, each type of container, container closure and equipment used should be initially perfomed validated with each operator participating in at least 1 consecutive successful APS and revalidated with one APS approximately every 6 months for each shift. Where manual connections and manipulations occur, clean room personnel performing these operations should be qualified for those operations and the APS for the process should be performed according to the guidance in the preceding sections. The APS bench also should include that used in the routine aseptic manufacturing process.</p>	<p>'Manual operation' has been replaced with 'manual filling and/or stopping' to clarify the intent of the section. In addition, 'validated' has been replaced with 'perfomed' to clarify that the APS does not validate the process or aspects of the process. A sentence focusing on manual connections and manipulations, where those filling and stopping has been added to clarify the intent of the section. It is difficult to interpret this section and intended requirements without understanding the context and scope of "manual operations" as it relates to the operations covered by Annex 1. For instance, the requirements for the manufacture of sterile ATMPs, which may include many manual operations, does not include similar requirements (see <i>Guidelines on Good Manufacturing Practice specific to Advanced Therapy Medicinal Products</i>). Explicit language required for what is required by "each type of container, container closure, and equipment used". "Each type" may be interpreted as the acceptable use of a family (for multiple equipment trainer motivations) or a matrix based (container and closure) approach may be applied for the purposes of APS. Note that this section also requires revalidation "with one APS approximately every 6 months" which is inconsistent with the requirement in the preceding section 5.61 that states "Normally, process simulation runs (periodic revalidation) should be repeated once a year (approximately every six months)..."</p>
2043	As currently written, the definition implies that and can be misinterpreted as the capability of the aseptic process is determined or tested through APS testing. Determination of capability through process design, rather than testing is a key principle of process control that is well articulated or implied in Annex 1, Annex 1A, and ICH Q7 through Q12.	<p>Aseptic Process Simulation (APS) – A simulation of the entire aseptic formulation and filling process in order to determine verify the capability of the process to ensure product quality.</p>	<p>'Determine' has been replaced with 'verify' to clarify the intent of the definition and align with the context statement made in section 5.34, as well as its usage elsewhere throughout the Annex.</p>

2001	The term "campaign" is used throughout Annex 1, however there currently is no definition for the term.	<p>Campaign - The manufacture of a series of batches of the same product in sequence in a given period of time followed by strict adherence to accepted control measures before moving to another product. The products are not at the same time but may be run on the same equipment.</p>	The definition for campaign is based on that defined for "campaigned manufacturer" from the WHO Guide to GMP for Medicinal Products Annex 2 glossary, as this term is used to cover the context as that within Annex 1.
2002	Having the definition in the glossary allows the reader to have mental access to the definition and reference.	<p>Cleanroom classification - A method of assessing the level of air cleanliness against a specification for a cleanroom or clean air equipment by measuring the non-viable airborne particulate concentration according to the method defined in ISO Standard 14644.1.</p> <p>i. "At rest" state - The condition whereby the installation of all the utilities is complete including any functioning HVAC, with the main manufacturing equipment installed as specified and standing by for operation, without personnel in the room.</p> <p>ii. "In operation" state - The condition where the installation of the cleanroom is complete, the HVAC system fully operational, equipment installed and functioning in the manufacturer's defined operating mode with the maximum number of personnel present performing or simulating routine operational work. In operation classification may be performed during simulated operation or during accept process simulation (where some case simulation is required).</p>	ISO 14644.1 is the consensus international standard for clean rooms and controlled environments and is referenced in Sec. 4.28. The Standard provides a consistent and universally accepted method for cleanroom classification and should be employed consistently across all regulated sites. Using ISO Standard 14644.1 will help prevent misinterpretation of the intent of the Annex. Added the definitions for both "at rest" and "in operation" states as also done in Section 4.11.
2003	The definition requires clarification relative to its use with SIP and SIB applications.	<p>Closed system - A system in which the sterile product is not exposed to the surrounding environment. For example, this can be achieved by the use of bulk product holders (such as tanks or bags) that are connected to each other by pipes or tubes as a system, with the system being installed after the connections are made. Examples of these can be (but are not limited to) large scale unitless and variable systems, such as those used in active substance manufacturing, or disposable single-use bag and manifold systems, such as those used in the manufacture of biological products. Closed systems, when used in this document, does not refer to systems such as BAFU or culture systems which are referred to as Isobaric Technologies.</p>	The example sentence describes also the connection of systems or process equipment with tubing, which typically describes a single-use process system. Such systems are not certified after connection, as these are generic installed pre-certified unit operations. Therefore, we suggest deleting the last part of the sentence. We added clarity with "maintenance" to the variable system and changed "disposable" to "single-use", as single-use is the global term used.

2014	As currently written, the definition can be confused with additional clarification. Contamination is defined as microbiological, chemical, or particulate contamination. A distinction should be made for microbiological contamination.	Contamination – The unaided introduction of impurities of a microbiological nature (quantity and type of microorganisms, spores) often referred to as bio-contamination/ bioburden as of foreign particulate matter, ions or ions a raw material, intermediate, active substance or drug product during production, sampling, packaging or repackaging, storage or transport with the potential to adversely impact product quality.	“Biocontamination” has been inserted in the definition to distinguish and reinforce a term often used in industry.
2020	As currently written, the definition may be misinterpreted as requiring that any and all contaminants be eliminated through decontamination. In addition, a distinction for microbiological contaminants should be considered to clarify the use of the definition throughout the Annex.	Decontamination – The overall process of removal or reduction of any contaminants (chemical waste, residue or microorganism) to a predetermined level from an area, object, or person. The method for decontamination used (e.g. cleaning, disinfection, sterilization) should be chosen and validated to achieve a level of cleanliness appropriate to the intended use of the area, decontaminant. Decontamination of contaminants from microorganisms is the by-product of microorganism activity is often referred to as bio-decontamination. This is otherwise much contamination used in the Annex implies bio-contamination.	“Any” has been removed and replaced with “to a predetermined level”, because it would not be feasible to achieve or demonstrate that any or all contaminants have been addressed in the decontamination process. In addition, a sentence has been added to reinforce that decontamination as used throughout the Annex primarily refers to the decontamination of microbiological contaminants. It is important to state and make that distinction to avoid misinterpretation of the intent of the Annex’s recommendations and requirements.
2024	Sterile and aseptic are used interchangeably throughout the document and therefore both terms require to be listed in the glossary.	Sterile Sterile / Aseptic Container device shall be a generic certified single-use aseptic container or a tube order.	The former glossary definition did not describe the typical sterile/aseptic connection detailed enough to be recognized as the generic certified single-use connection. It could have been misinterpreted as the standard used anyway though as aseptic/aseptic connection.

2007	<p>In currently written may for use prescription, we would suggest removing the example of (> 20 percent) as it may be misleading.</p>	<p>Isobaric sampling head - A sampling head designed to draw the air as fast as possible so that the more particulates go into the sample so would have passed the area if the sample had been taken there i.e. the sampling condition in which the mean velocity of the air entering the sample probe inlet is nearly the same (> 20 percent) as the mean velocity of the airflow at that location.</p>	<p>The description of "... the mean velocity of the air entering the sample probe inlet is nearly the same (> 20 percent) as the mean velocity of the airflow at that location..." can give an unnecessarily strict interpretation by inspectors.</p>
2008	<p>The definition requires additional wording to reference its practical usage by industry.</p>	<p>Isobaric - A controlled, discontinuous environment meeting Class 4 (ISO 5) conditions used the aseptic process manufacturing that provides an unsegmented, continuous isolation of its interior from the external environment. Once discontinuous by a radiation cycle, an isobaric process the microbiological contamination of sterile products and product contact surfaces of the interior by rigid wall enclosures and the supply of continuous, controlled replacement of HEPA filtered air.</p>	<p>The current definition is aligned with a PDA definition that is linked to the practical usage of isobaric in the industry and helps the reader understand the important aspects of the isobaric.</p>
2008	<p>Current definition requires modification to distinguish processes that are used to fill product from processes that are used to prepare or manipulate sterile product.</p>	<p>Manual aseptic filling - An aseptic filling process where the operator manually places, fills, and/or seals an open container with sterile product. Intervention is required to complete the filling of each container in a, as occurs during aseptic compounding operations).</p> <p>Manual aseptic operation - An aseptic process where operator manually performs activities on or to an open container, bag, or unit that contains sterile product.</p>	<p>Manual aseptic filling usually refers to the filling of small quantities of product, where used automated lines are not suitable. While manual operations may include other aseptic manipulations performed the J17899 and other process, such as connections, mixing, pipetting, heat sealing, etc. Separate definitions are needed, because the controls required for filling and operations are different. "Manual operations" are identified in Section 3.11 with the examples provided of "aseptic compounding or filling". Manual processes are also identified in other sections of the Annex, e.g., Section 5.122.iii, refers to "The increase in the number and complexity of manual operations" and Section 5.129 which refers to "critical manual handling operations". The glossary currently only defines the specific term "manual filling" which is not inclusive of other manual aseptic processes or operations that may be performed.</p>
